Of the ten papers, only two do not admit experimenting with the regressions, sometimes with hundreds of different specifications. None propose to alter their levels of significance. Only two of the ten do not use a sign test in conjunction with a significance test: the variable has a statistically significant coefficient *and the right (or expected) sign*. Little statistical theory seems to lie behind the practice, although it seems sensible enough—a beginning, indeed, of looking beyond statistical significance to the size of the coefficient. One of the papers uses a sample of convenience so convenient that it looks like a universe, about which sampling theory can tell nothing: all counties in Alabama, Mississippi, North Carolina, and South Carolina. Four of the ten use true samples, such as the opinions of 6,000 Swedes on the current and expected rate of inflation. The only doubt here is the disproportion of effort in dealing with sampling errors when others are probably more serious. At  $N = 6000$  we can surely dismiss Student and attend to bias. As Leamer remarked recently, "when the sampling uncertainty... gets small

compared to the misspecification uncertainty... it is time to look for other forms of evidence, experiments, or nonexperiments" (1983, p. 33). The other five papers use time-series. One can only ask quietly and pass on: from what universe is a time-series a random sample, and if there is such a universe, is it one we wish to know about?

The most important question is whether the economists in the sample mix up statistical and substantive significance. Even on purely statistical grounds the news is not good: none of the papers mention the word "power," though all mention "significance." Statisticians routinely advise examining the power function, but economists do not follow the advice. Some follow its spirit, avoiding the excessive gullibility of the type II error by treating the machinery of hypothesis testing with a certain reserve. Most do not. Only three of the ten do not jump with abandon from statistical to substantive significance. The very language, though mostly formulaic, sometimes exposes the underlying attitude. One paper slipped into using the phrase "statistically important."

Seven of the papers, then, let statistical significance do the work of substantive significance. Usually this is accomplished by a fallacy of equivocation. The result on page 10 that is (statistically) significant turns up as (economically) significant on p. 20. In the worst cases there is no attempt to show how large the effects are, or whether the statistical tests of their largeness are powerful, or what standard of largeness one should use. In four of the seven papers with significant errors in the use of significance there is some discussion of how large a coefficient would need to be to be large, but even these let statistical significance do most of the work. And even in the three papers that recognize the distinction and apply it consistently, there is flirtation with intellectual disaster. The siren song of "significance" is a hazard to navigation.

#### IV. What is to be Done?

If we do not wish to leave science to chance, we must rethink the use of statistical significance in economics. Econometrics

courses should teach the relevant decision theory, as judging from results they appear not now to do. It would help if the standard statistical programs did not generate *t*-statistics in such profusion. The programs might be written to ask "Do you really have a probability sample?," "Have you considered power?," and, above all, "By what standard would you judge a fitted coefficient large or small?" Or perhaps they could merely say, printed in bold capitals beside each equation, "So What Else is New?"

# Macroeconometric Modeling and the Theory of the Representative Agent

By JOHN GEWEKE\*

The Lucas critique of econometric policy evaluation (1976) argues that, to the extent econometric models do not capture the primitive parameters of tastes and technology, their coefficients can be expected to vary with changes in policy regimes. Several econometricians have undertaken empirical work that separates the parameters of tastes, technology, and policy, estimating models that are in principle immune from this critique. Exemplary contributors to this effort have been Thomas Sargent (1978) and Sargent and Lars Hansen (1980). The empirical work inspired by the Lucas critique has proceeded using representative agent models and aggregate data. The treatment of expectations and dynamic optimization has been careful, although at times necessarily limited by the analytical requirements of attaining closed-form solutions for dynamic programming problems under uncertainty. Potential problems due to aggregation have usually been ignored, although when preferences and technology are quadratic it appears that they can be disposed of quickly: "assuming a representative firm is only a convenience, as the model admits a tidy theory of aggregation" (Sargent, 1978, p. 1016).

It is ironic that a paradigm that emphasizes the isolation of the primitive parameters of tastes and technology has led to empirical work that has been conducted almost exclusively with aggregate data. (There are exceptions: T. MaCurdy, 1983; J. Biddle, 1984.) There are several difficulties with this development. First, the fact that representative agent models with exact aggregation *can* be constructed is unrelated to whether or

not these models are adequate; we can also construct models in which agents' behavior is unaffected by the policy regime. To exclusively model and test one but not the other appears to be a misplacement of emphasis. Second, some of this work has proceeded using representative agents whose behavior cannot be aggregated exactly (see, M. Eichenbaum, Hansen, and Kenneth Singleton, 1984, for an example).

There is a third and most fundamental objection to empirical work which seeks to avoid the Lucas critique, yet uses aggregate data. Whenever econometric policy evaluation is undertaken using models estimated with aggregate data, it is implicitly presumed that the aggregator function is structural with respect to the policy intervention in question. Formally, aggregator functions are no more structural than are within-regime, reduced-form relations of endogenous to policy variables. As a modeling strategy, ignoring the sensitivity of aggregators to policy changes seems no more compelling than ignoring the dependence of expectations on the policy regime.

This paper describes a very modest econometric model in which the effects of ignoring aggregation and of ignoring expectations, each within the context of several representative agent models, can be appreciated. Objective functions are quadratic and prices are disparate across agents; in these respects the model's assumptions are in the mainstream of Lucas and subsequent empirical work. The model is carefully contrived so that exact aggregation is always possible. This is not essential to the argument in any way, but it drastically reduces the number of circumstances to be examined in constructing numerical examples. The example pertains to neoclassical production, and in each case there are three distinct representative agents: one for production, one for factor demand,

\*Professor of Economics, Duke University, Durham, NC 27706. Financial support from NSF Grant SES-8318778 and a Sloan Research Fellowship are gratefully acknowledged. A more detailed version of this paper is available on request from the author.

and one for supply. The three are not the same, and except for one easily understood exceptional case, all three give different and incorrect evaluations of the effect (here, on output) of a policy change (here, a subsidy). Numerical examples suggest that the aggregation and expectations problems are of about the same order of magnitude.

### I. Representative Agents and Aggregation over Prices

A small industry in a small country produces a single, homogeneous output  $y$  ultimately sold competitively in a world market. Output is produced using a single variable factor  $x$  that is purchased competitively in the domestic market. The production technology is the same in all firms in the industry: for the  $i$ th firm at time  $t$ ,  $y_{it} = ax_{it} + dx_{it}^2$ ;  $a > 0$ ,  $d < 0$ . Firms are geographically distributed throughout the small country, and because of this the price for the output of the  $i$ th firm is  $p_{it}$ , the price varying, say, with access to deep-water ports. Output price changes through time but relative output prices across firms never change,  $p_{it} = p_t p_i$ , as would be the case if price differentials were due to different transportation costs and the relative prices of output and transportation were unchanging. To normalize take  $E(p_i) = 1$  and assume  $E(p_i^j) = m_j$  exists for  $j = -3, -2, \dots, 2$ . Input price  $r_t$  is the same for all firms. Firms maximize current-period profits, so the  $i$ th firm's factor demand is  $x_{it} = -a/2d + (1/2d)r_t/p_{it}$  and its supply function is  $y_{it} = -a^2/4d + (1/4d)r_t^2/p_{it}^2$ .

An econometrician has available the aggregate time-series  $p_t$ , which is the average price received;  $y_t$ , the average output of a firm, and  $x_t$ , the average factor input of a firm, for  $t = 1, \dots, T$ . The aggregate supply function is  $y_t = -a^2/4d + (m_{-2}/4d)r_t^2/p_t^2$ , the aggregate factor-demand function is  $x_t = -a/2d + (m_{-1}/2d)r_t/p_t$ , and the aggregate production function is

$$y_t = -\left(\frac{a^2}{4d}\right)\left[m_{-2}/m_{-1}^2 - 1\right] \\ + \left(m_{-2}/m_{-1}^2\right)ax_t + \left(m_{-2}/m_{-1}^2\right)dx_t^2.$$

The seriousness of any misspecification can be gauged only in relation to the purposes for which the model is used. To that end, suppose the econometrician's model estimated with aggregate time-series is used to evaluate the effect of a subsidy on output. Consider two subsidy schemes: an ad valorem policy in which the firm faces the price  $sp_{it}$ ,  $s > 1$ , and an ad rem policy in which the price becomes  $p_{it} + u$ ,  $u > 0$ . Actual output with the ad valorem subsidy will be indicated correctly by the aggregate supply function with  $sp_t$  used in lieu of  $p_t$ :  $y_t = -a^2/4d + (m_{-2}/4d)r_t^2/(sp_t)^2$ . Hence the actual effect of an ad valorem subsidy  $s$  on output, when factor price is  $r_t$  and aggregate output price is  $p_t$ , is  $(s^{-2} - 1)(m_{-2}/4d)(r_t^2/p_t^2)$ . Since the aggregate supply function is exact and the subsidy represents no change in the distribution of output prices across firms that previously prevailed, this is unsurprising. If the effects of the subsidy are inferred from the representative agent for the aggregate factor-demand function then the anticipated effect is  $(s^{-2} - 1)m_{-1}r_t^2/(4dp_t^2)$ , and the ratio of the anticipated to the actual effect is  $m_{-1}/m_{-2} < 1$ . If the effects of the subsidy are inferred from the representative agent for the aggregate production function, then the ratio of the anticipated to the actual effect is  $m_{-1}^2/m_{-2}^2$ .

None of the three representative agents provides a correct evaluation of the effect of an ad rem subsidy. Actual output with ad rem subsidy  $u$  is  $y_t = -a^2/4d + (r_t^2/4dp_t^2)E[p_i + (u/p_i)]^{-2}$ . Hence the effect of the subsidy  $u$  on aggregate output  $y$  in period  $t$  is  $(r_t^2/4dp_t^2)E\{[p_i + (u/p_i)]^{-2} - p_i^{-2}\}$ . The anticipated effects, using our three representative agents, are  $(m_{-2}r_t^2/4dp_t^2)\{[1 + (u/p_t)]^{-2} - 1\}$  from the aggregate supply function;  $(m_{-1}r_t^2/4dp_t^2)\{[1 + (u/p_t)]^{-2} - 1\}$  from the aggregate factor-demand function; and  $(m_{-1}^2m_{-2}^2r_t^2/4dp_t^2)\{[1 + (u/p_t)]^{-2} - 1\}$  from the aggregate production function. The ratios of the anticipated effects to one another are the same as for the ad valorem subsidy. Standard Taylor-series methods show that the ratios of anticipated effects to true ones are  $m_{-2}/m_{-3}$ ,  $m_{-1}/m_{-3}$ , and  $m_{-1}^2/m_{-2}m_{-3}$ , respectively, for small  $u$ ; all are less than one.

## II. Representative Agents and Price Expectations

Problems of a similar kind arise when firms plan production based on anticipated rather than actual prices, but the econometrician ignores this fact. Suppose that firms now receive the same price  $p_t$  for their output, but must choose  $x_t$  one period prior to observing  $r_t$  and  $p_t$ . Firms maximize  $E(\pi_t/p_t) = ax_t + dx_t^2 - E(r_t/p_t)x_t$ , and  $E(r_t/p_t) = \alpha + \beta(r_{t-1}/p_{t-1})$ ,  $0 < \beta < 1$ ,  $\text{var}(r_t/p_t) = \sigma^2$ . The sequence  $\{p_t\}$  is independently and identically distributed with mean 1 and is independent of the sequence  $\{r_t/p_t\}$ . Without loss of generality assume that the unconditional expectation of  $r_t/p_t$  is 1, whence  $\alpha + \beta = 1$ . The factor-demand function is  $x_t = (\alpha - a)/2d + (\beta/2d)(r_{t-1}/p_{t-1})$  and the supply function is  $y_t = (\alpha^2 - a^2)/4d + (\alpha\beta/2d)(r_{t-1}/p_{t-1}) + (\beta^2/4d)(r_{t-1}/p_{t-1})^2$ .

Suppose an econometrician estimates the production, factor-demand, and/or supply equations, but assumes that firms make decisions as if previous-period prices would persist in the next period, rather than using previous-period prices to forecast the prices of the next period. If the factor-demand function is assumed to be representative, the econometrician will construct the supply function  $\hat{y}_t = -(a - \alpha)^2/4d\beta + (\beta/4d)(r_{t-1}^2/p_{t-1}^2)$ ; from the production function, he will construct  $\hat{y}_t = -a^2/4d + (1/4d)(r_{t-1}^2/p_{t-1}^2)$ .

Now consider the imposition of an ad valorem output subsidy. Using the methods of the previous section, the average effect of the subsidy on output will actually be  $[(s^{-2} - 1)/4d](1 + \beta^2\sigma^2)$ . But under the assumption of a representative agent the anticipated effect will be  $[(s^{-2} - 1)/4d](2\alpha\beta + \beta^2 + \beta^2\sigma^2)$  using the supply function;  $[(s^{-2} - 1)/4d]\beta(1 + \sigma^2)$  using the factor-demand function; and  $[(s^{-2} - 1)/4d](1 + \sigma^2)$  using the production function. The anticipated effect using the production function overstates the actual effect, on average, while that using the supply function understates it; and except for unreasonably large values of  $\text{var}(r_{t-1}/p_{t-1})$  the anticipated effect using the factor-demand function typically understates the true effect. With an ad rem sub-

sidy, the average effect of the subsidy on output will be  $[(g^2(u) - 1)/4d](1 + \beta^2\sigma^2)$ , with  $g(u) = E[p_t/(p_t + u)]$ . The anticipated effect will be  $(\alpha\beta/2d)[g(u) - 1] + [\beta^2(1 + \sigma^2)/4d][h(u) - 1]$  using the supply function;  $[\beta(1 + \sigma^2)/4d][h(u) - 1]$  using the factor-demand function;  $[(1 + \sigma^2)/4d][h(u) - 1]$  using the production function; with  $h(u) = E[p_t^2/(p_t + u)^2]$ .

## III. Some Numerical Examples

The importance of the representative agent and aggregation problems taken up in this paper can perhaps best be appreciated by constructing some numerical examples. Table 1 provides the ratios of anticipated to actual effects of subsidies when prices are distributed uniformly on  $[1 - v, 1 + v]$ . As one would expect the results are quite sensitive to the size of  $v$ . The value  $v = .01$  is surely a lower bound; .10 may be reasonable for local areas (George Stigler, 1961) while price dispersion over larger areas may be greater. When  $v = .2$ , the highest price is half again as high as the lowest, and when  $v = .5$ , this ratio rises to three. The latter ratio is implausibly large for actual selling prices, but in other, common circumstances may be realistic—for example, when some firms sell retail and others wholesale, or when the effective selling price is anticipated based on information that is not the same for all firms.

The supply function in the ad valorem case is perfectly adequate because an ad valorem subsidy does nothing to distort the distribution of relative selling prices across firms, in our model. When an ad rem subsidy is introduced the distribution of prices is shifted upward, but the aggregate model imputes to the subsidy an increase in the dispersion of prices across firms which in fact does not occur. Since supply is a convex function of selling price, this leads to an underestimate of the effects of the subsidy. As  $u$  increases, this convexity becomes less important, and hence ratios always vary directly with  $u$ . The production function representative agent model performs the worst here because the aggregate production function reflects a compounding of the relationship of output to factor prices, and of factor

TABLE 1—RATIOS OF ANTICIPATED TO ACTUAL EFFECTS, AGGREGATION OVER PRICES<sup>a</sup>

$v$	Supply Function	Factor Demand	Production Function
A. Ad Valorem Subsidy			
.01	1.0000	.9999	.9999
.10	1.0000	.9933	.9867
.20	1.0000	.9731	.9470
.50	1.0000	.8240	.6789
B. Ad Rem Subsidy ( $u/p_t = .20$ )			
.01	.9999	.9999	.9998
.10	.9931	.9864	.9798
.20	.9722	.9461	.9207
.50	.8264	.6809	.5610

<sup>a</sup>Distribution of prices across firms is uniform on  $[1-v, 1+v]$ .

prices to inputs; at each step, the convexity of the relevant function introduces downward bias due to aggregation.

Providing representative examples in the price expectations model is simplified by the fact that results depend only on  $\beta$ , given reasonable values of the other parameters. What is a reasonable value of  $\beta$  depends on the inherent volatility in  $r_t/p_t$ , and the length of the decision period (for a month, .99 might be reasonable; for a year, .75). The outstanding feature of Table 2 is that the production function representative agent model provides an accurate indication of the effects of a subsidy on output, in situations in which the other two models do not. This result emerges because the aggregate production function is not influenced by the expectations process, whereas the other two aggregate models are. The derived supply function is correct for deterministic changes in prices, and the imposition of a subsidy is very nearly that: the only source of discrepancy in this model stems from the use of  $r_{t-1}/p_{t-1}$  rather than  $\beta r_{t-1}/p_{t-1}$  in evaluating the effects of the subsidy on average, and with standard deviations in prices modest relative to their means, that is unimportant.

#### IV. Conclusion

My example has illustrated several facts. Perhaps the most important is the similarity between the dependence of expectations for-

TABLE 2—RATIOS OF EXPECTED ANTICIPATED TO EXPECTED ACTUAL EFFECTS, PRICE EXPECTATIONS<sup>a</sup>

$\beta$	Supply Function	Factor Demand	Production Function
A. Ad Valorem Subsidy or Ad Rem (small $u$ )			
.99	.9999	.9908	1.0008
.95	.9976	.9536	1.0038
.90	.9903	.9066	1.0074
.75	.9389	.7628	1.0171
.50	.7525	.5149	1.0297
B. Ad Rem Subsidy ( $u = .50$ )			
.99	.9904	.9888	.9988
.95	.9593	.9517	1.0018
.90	.9192	.9049	1.0054
.75	.7915	.7614	1.0152
.50	.6270	.5138	1.0277

<sup>a</sup>In all instances  $\sigma = .20$ , and in figuring  $g(u)$  and  $h(u)$  for the right panel the distribution of  $p_t$  is taken to be uniform on  $(.75, 1.25)$ .

mation on policy regime and the dependence of aggregators on policy regime. In the aggregation example with disparate prices across firms, ratios of output prices between specific firms never changed. An ad valorem subsidy preserved that relationship, and hence the aggregator, and so could be evaluated properly using the aggregate supply function from the period with no subsidy. An ad rem subsidy changed the cross-firm output price relationships and the aggregators, and its effect on output was evaluated incorrectly with all representative agent models.

The example shows that it can make a difference *which* representative agent is used, even when aggregation is exact. Aggregators are *not* the same for production, factor demand and supply; the familiar cross-equation restrictions of neoclassical production theory fail and will lead to computational dilemmas. The same problem arises when expectations are ignored. It would be very useful to state with some generality which representative agent is likely to be more reliable in these and other circumstances, but that is likely a difficult undertaking and clearly beyond the purview of this paper.

Finally, these numerical examples show that at least one situation can be constructed in which the perils of ignoring aggregation

are of the same order of magnitude as those of ignoring expectations. Since the example is constructed, any semblance between this finding and difficulties with real data may be purely coincidental. But it does suggest that in the attempt to build econometric models with primitive parameters of tastes and technology, it may be useful to treat aggregation more explicitly than is usually done in these efforts.

## MODELING INTERCOUNTRY LINKAGES<sup>†</sup>

### An Integrated Accounting Matrix for Canada and the United States

By JACOB COHEN AND STEVEN HUSTED\*

In the past two decades, considerable progress has been made in studying the economic relationships between countries through the linkage of large-scale national econometric models. Examples of these projects include Project Link, the RDX2-MPS experiments of the Bank of Canada, and the multicountry model of the Federal Reserve Board. While these models tell us much, they typically suffer from several important problems. First, the linkages are often incomplete. In some cases the separate country models may only be linked via the trade accounts. Or, if capital and factor flows are considered, they are modeled in only a highly aggregated fashion. Second, as Ray Fair (1979) has noted, no model does an adequate job of linking the underlying sectoral flows of funds accounts with the national income accounts. Therefore, in the interest of modeling aggregate relationships, underlying balance sheet constraints may be violated or ignored. This could have, Fair argues, important consequences for empirical results.<sup>1</sup>

In this paper we suggest our own strategy for modeling the economic linkages between any two countries. Our strategy focuses on the underlying flows between these two countries and the sectoral contributions to these flows. That is, we propose to merge the flow of funds accounts via their bilateral balance of payments. We envision an integrated flow of funds accounting framework with the two countries sharing a common balance of payments. This modeling strategy has several advantages. First, our suggested framework could be used, following the strategy of Fair, to supply the financial underpinning for future economic modeling of international linkages of prices and interest rates. The balance sheet constraints inherent in the framework will impart additional information in any statistical estimation of such a model. Second, this strategy should yield a better understanding of a country's balance of payments since it necessarily links domestic decision making with its international outcome. Third, our framework should be useful to policymakers since it would allow them to model the underlying financial implications of proposed policy changes. Finally, the implementation of our proposal could lead to improved accuracy in balance of payments statements.

<sup>†</sup>*Discussant:* John A. Sawyer, University of Toronto.

\*Department of Economics, University of Pittsburgh, Pittsburgh, PA 15260. Too numerous to mention are the individuals who have offered suggestions and statistical assistance. Two who must be singled out, however, are Gerry Gravel and John Motala of Statistics Canada. We are also indebted to Douglas Case for research assistance. Financial support was provided by the University Center for International Studies, University of Pittsburgh and the Canadian Embassy, Washington, D.C.

<sup>1</sup>Fair demonstrates this point via a hypothetical example. In this example, he duplicates his own econometric model of the United States which includes sectoral financial balance sheet constraints for four economic sectors. The sectors Fair considers are households, firms, banking, and government. Then, he links the two models

so that his "world" is composed of two identical countries wherein all flows of funds between the two countries are accounted for and the exchange rate is endogenously determined. Using this model, Fair goes on to simulate the effects of a variety of economic shocks under varying assumptions about capital mobility and exchange rate regime.

### I. Conceptual Framework

Both the United States and Canada maintain and report detailed flow of funds (*FOF*) accounts. The Federal Reserve is responsible for constructing the U.S. accounts. In Canada, the accounts are prepared by Statistics Canada. The lack of Bank of Canada involvement creates data problems.

The *FOF* accounts report financial and nonfinancial activities for various sectors and subsectors of the economy (for example, households, business, government, commercial banks, nonbank financial institutions, monetary authority, rest of the world). The classification is institutional rather than functional. That is, the sectors are decision-making sectors. In the business sector, where this matters most, corporations are the organizational unit rather than operating plants. If establishment-institutional matrices could be constructed, production decisions could be linked with the financial decisions of the corporation. Moreover, this would permit disaggregation of the business sector so that interindustry flows could be recorded. To date, such linkages have not been achieved for either the United States or Canada.

The summary transactions matrix prepared in both countries shows sectors down the columns and transactions across the rows. Nonfinancial transactions are reported first and consist of saving entries (credits) and capital outlays (debits) derived from the national income and product accounts. Next follow the financial transactions rows which include detail on financial uses (debits) and sources (credits) of funds or in an alternative (Canadian) terminology, detail on increases in financial assets and liabilities. There are important differences in transaction and sector coverage in the two sets of accounts. Consumer durables are included in U.S. capital outlays, but not in Canadian. Government capital acquisition and net purchases of existing assets are included in Canadian nonfinancial capital acquisitions but not in the U.S. acquisitions. In the financial rows, claims on associated enterprises are part of the Canadian accounts, but not the U.S. accounts. Also, the Canadian accounts break out public financial institutions, social secur-

ity funds, nongovernment enterprises from the government sectors. Persons and unincorporated business are combined in the Canadian data, but are separated in the U.S. accounts.

Across all sectors, saving and capital outlays are equal. For individual sectors, the identity is between gross investment (capital outlays and net financial investment) and gross saving. Net financial investment (financial uses less financial sources) over all sectors is zero.

In addition to these flow of funds constraints, an integrated two-country matrix introduces a set of *FOF* identities based on the bilateral balance of payments. Once transactions are stated in a common currency, the debit (credit) items for the U.S. subsector of the Canadian rest of the world sector will have a counterpart in the credit (debit) items of the Canadian subsector of the U.S. rest of the world sector. In schematic form, an integrated matrix will enter the second country sectors in reverse order so that one rest of the world sector and its mirror image lie alongside each other.

The *FOF* accounts are subject to various kinds of statistical errors and inconsistencies: in valuation bases, in timing, in classification of transactions and omissions of pertinent transactions or transactors from the accounts. For the *FOF* constraints to hold, balancing statistical discrepancy rows and columns must be introduced. The sum of sector discrepancies (called the residual error of estimate in the Canadian accounts) equals the sum of transactions discrepancies. A large statistical discrepancy for the household (persons and unincorporated business) and rest of the world sectors is a feature of both sets of accounts. A strong correlation has been found in the U.S. accounts between these discrepancies. Errors in the capital flows estimates have their counterpart in estimates of household acquisition of financial assets (Frank de Leeuw, 1984). A reduction in statistical discrepancy for the rest of the world sector by reconciliation of the Canadian and U.S. balance of payments may improve household estimates and contribute to a reduction in overall discrepancy for both countries.

Despite apparent differences in the calculation of statistical discrepancy, Canadian and U.S. accountants looking at the same data will arrive at identical discrepancy measures. This is because statistical discrepancy is uniformly defined in terms of the inequality of gross saving (*GS*) and gross investment (*GI*) (over all and for each sector). Gross investment is the sum of capital outlays (*CO*) and net financial investment (*NFI*). Hence, statistical discrepancy (*SD*) is calculated according to the following formula:

$$SD = GS - GI = GS - CO - NFI.$$

Over all sectors, the U.S. statistical discrepancy reflects both the discrepancy in the national income accounts and the discrepancy in net financial investment. In the Canadian accounts, in contrast, financial debits and credits for given transactions are forced into balance so that net financial investment is zero. This process requires that the Canadian statistician reestimate gross saving or capital outlays. The end result of this adjustment is that the original discrepancy between *GS* and *GI* will be left unaffected.

## II. Estimation Problems

Our goal is to merge the two *FOF* accounts into a single matrix. In order to achieve this goal, a number of estimation problems must be overcome. First, it is necessary to have a uniform transaction classification for the two countries. The financial transactions lines necessarily distinguish between Canadian, U.S., and rest of the world financial instruments. A Canadian instrument can be bought or sold in all three markets and the same for U.S. and third-country instruments. In some cases, transactions do not match up across countries (for example, claims on associated enterprise) necessitating consolidation of categories.

Unlike the necessary uniformity of transaction coverage, institutional sectoring can reflect national differences. The only required matching is in the rest of the world sector, which will now be split into U.S. and

third-country sectors for Canada, and Canada and third-country sectors for the United States.

Breaking the foreign sectors of the two *FOF* accounts into the "second" country (i.e., the U.S. or Canada) and the "rest" of the rest of the world poses one of the major challenges to our modeling effort. This is because this breakdown is not made in the published *FOF* accounts of either country. Consequently, we must look to other sources such as each countries' bilateral balance of payments for the necessary data. But the detailed categories in the balance of payments lack a one-to-one correspondence with the *FOF* transactions. Assigning U.S. figures in the Canadian balance of payments to the *FOF* transactions categories produces residual rest of the world values in the *FOF* that have no resemblance to the counterpart third-country flows in the Canadian balance of payments. Statistics Canada kindly provided a reconciliation of *FOF* and the balance of payments with the U.S. broken out for 1981 but without some methodology a continuous time series for the U.S. subsector could not be constructed. We skirted this problem by forecasting only three main aggregates for the rest of the world subsectors—saving, capital outlays (transactions in existing intangible assets), and net financial investment. This seemed to provide reasonable consistency between the *FOF* accounts and the balance of payments data on which we had to rely.

A second major challenge in the use of balance of payments data is reconciling the statements of the two countries. Both the United States and Canada have long published detailed bilateral balance of payments statements. For a variety of reasons, the reported data on major line items seldom match and, in fact, the mismatches are often very large. Rising concerns in the 1960's over this problem led to the creation of the Technical Working Group on Canada-U.S. Balance of Payments in 1963. Annual reconciliation of the current account during 1968-71 was based on the work of this committee and since 1971 on that of the United States-Canada Trade Statistics Committee. Their detailed reconciliation of trade flows in 1974

reveals three main kinds of discrepancy—geographical classification, transactions classification, and a catchall category which includes nonreceipt of documents, timing, and valuation differences and errors (Statistics Canada, 1981, p. 301). The adjustments were large enough in 1969 so that the U.S. perception of its current account position with Canada shifted from a deficit to surplus.

Reconciliation figures have yet to be produced for the capital accounts. Differences in the amount of detail are one difficulty. Problems are in part conceptual such as with the treatment of U.S. branches of Canadian insurance companies. Both the United States and Canada treat these branches as nonresidents. A study for 1972 pinpoints differing estimates of short-term capital flows as the main source of the bilateral discrepancy (Statistics Canada, p. 308). The “third-country” problem also contributes to errors in the bilateral data. Such errors arise from settlement via third countries (“multilateral settlement”). For example, a Canadian importer pays a European exporter with U.S. dollar balances. As a result the bilateral balance of payments for all three countries will be thrown out of balance.

The difficulty in reconciling the bilateral accounts is perhaps best illustrated by comparing the signs on the errors and omissions entries in the two bilateral accounts. An “outward” discrepancy (net debits) for one country is not matched by an “inward” discrepancy (net credits) for the other country. Over the period 1946–74, the annual signs were the same in 17 of 29 cases (Statistics Canada, pp. 166–67). Reconciliation of the capital accounts is a separate research exercise. For the present we are relying on the more detailed Canadian data in estimating the integrated matrix.

### III. Forecasting the Matrix

Once we had a feel for the contours of the matrix, we set about to forecast the cells for the year 1985. A possible first step in constructing such a forecast would be to examine the existing large scale models of the United States and Canada for clues as to

how to model statistically nonfinancial and financial flows. If one were to use these equations and then rely on judgment and the adding-up constraints inherent in the model, then the only additional information required would be a set of predicted values of the exogenous variables of the system.

An alternative procedure and the one we employed in our work is to forecast the matrix using predictions generated from simple time series models of the data. At first, we forecast both detailed component entries of the *FOF* accounts and the aggregates of these components. This led to the problem that the sum of the forecasts of the component parts did not equal the forecast of the aggregate. Faced with the inevitability of a proliferation of discrepancy balancing items, we used only the forecasts of the main aggregates for the integrated matrix. These aggregates were gross saving, nonfinancial capital acquisition (outlays), net financial investment, net increase in financial assets, net increase in liabilities, and statistical discrepancy. (As previously stated, only three aggregates were forecast for the rest of the world sector.) Forecasting net financial investment in addition to its components provided a way of residually estimating either financial uses or sources when the predicted value was shaky. For each sectoral aggregate, simple distributed lag equations containing alternately one and two lags were fitted to the historical data. Because the aggregated data often evolve slowly over time, this exercise commonly yielded prediction equations with  $R^2$  exceeding .90. Credence to this approach is given by the often recorded success of time-series methods in economic studies (albeit more sophisticated than our own) over other more complicated forecasting techniques. A major problem with this technique, however, is that it is incapable of predicting major turning points in the data. Because of this, once such a turning point has been missed, this error is factored into subsequent forecasts.

A point of interest was the general deterioration in our results when we applied our forecasting methodology to changes in individual assets and liabilities. An implica-

tion of this is that the larger magnitudes such as capital outlays are flow constrained (the lagged values are proxies for income or external finance), while detailed portfolio decisions are price (interest) constrained.

Once the forecasts had been generated, they were entered into the matrix. Here judgment was required since the adding-up constraints were necessarily violated by the independent forecasts. At least one of the forecast values would have to be adjusted for each sector and each row. An iterative procedure in adjusting the rows and columns of the matrix was followed. The direction of adjustment was in line with the historical trends in the series. This method is similar to the method of successive approximations employed by the Federal Reserve in its flow of funds projections. Our application of this technique simultaneously to two countries is a point of departure. Another point of departure from the Fed's procedures was our recognition of the inevitability of statistical discrepancy and treating it as another variable.

We found in constructing our forecasts that frequently the discrepancy forecast was more reliable than the individual financial and nonfinancial transaction forecasts. This was especially true of the discrepancies in the U.S. *FOF* accounts where we obtained  $R^2$  values exceeding .6 in seven of fourteen sectors. When we estimated equations for rest of the world discrepancies for both countries we found that interest rate differentials, trade flows and the level of direct foreign investment contributed significantly to explaining these variables. (For more detail on this point see our 1984 paper). Hence, instead of treating the discrepancy as zero *ex ante*, other flows could be predicted residually once the discrepancy had been forecast. In those cases where we were not confident of our discrepancy estimate, it was generated residually.

While our forecasts cannot be reported fully here, an inkling of what they are like is suggested by our forecasts of the disaggregated rest of the world subsectors for Canada and the United States for 1985. (In constructing our forecasts we used annual data

for the period 1950–83 for the United States and, 1960–83 for Canada.)

Expressed in millions of U.S. dollars (on the basis of an exchange rate of .79), we forecast the following for the U.S. subsector of the Canadian matrix (numbers in parentheses are 1983 values): gross saving (credit entry), -616 (1578); nonfinancial capital acquisition (debit), -46 (-50); net financial investment (debit), 408 (1240); discrepancy (debit) -978 (388).<sup>2</sup> (The last value was forecast rather than residually determined.) Taken together, these values imply that Canada will have a current account surplus with the United States but, because of the size of the forecast discrepancy, the United States will have a positive net financial investment in Canada. For the foreign rest of the world subsector for Canada we forecast: gross saving, 771 (-2214); nonfinancial capital acquisition 241 (676); net financial investment 4592 (2748); discrepancy -4062 (-5638). For the foreign rest of the world subsector for the United States we forecast: gross saving 68935 (33875); nonfinancial capital acquisition -46 (-50); net financial investment 68787 (31543); and discrepancy 204 (2382). Taken as a whole, our forecast of the 1985 U.S. balance of payments suggests a current account deficit of about \$70 billion, approximately twice the 1983 level.<sup>3</sup>

#### IV. Future Work

The work to date has been an exercise in filling the cells of an integrated two-country *FOF* matrix. We do not have a great deal of

<sup>2</sup>Recall that these numbers will appear with the opposite sign in the Canadian subsector of the U.S. portion of the matrix. Nonfinancial capital acquisition in the *FOF* rest of the world sector for Canada is limited to "inheritances and immigrants' funds" as reported in the Canadian balance of payments data. Receipts and payments were netted against each other vis-à-vis the United States with the residual assigned to the "foreign" sector. The U.S. *FOF* matrix does not record such transactions.

<sup>3</sup>The U.S. rest of the world forecasts were generated under the assumption of a 1984 current account deficit of \$100 billion rather than using the forecast deficit for 1984, based on the autoregressive equations.

confidence that estimation by autoregressive models and subsequent iteration will provide good forecasts of either 1984 or 1985. But, it is a beginning for more sophisticated work. A possible next step would be the fitting of simultaneous econometric equations to provide a genuine flow of funds behavioral model. The end result would be a structure similar to Fair's, but with a more-detailed financial underpinning. We caution however that equations based on flow of funds accounts have special problems. Outside the estimation period the tracking performance is often unsatisfactory. The fragility of financial equations has many explanations—financial innovation, the speed with which financial markets can adjust to changes in rates, and most importantly the inadequate modeling of market expectations. Therefore, any forecasting effort should follow a modest approach which combines the discipline of the flow of funds with "judgment" and selective econometric estimation.

Until reconciliation of the bilateral capital accounts, model building of the type we have proposed will probably have to rely upon one set of balance of payments data and impose it on the second country. Reconciliation has to be a government affair although the outside economist can be of use in outlining the conceptual problems that would be

faced and suggesting testable hypotheses. If the Canadian and U.S. governments can be encouraged to tackle the discrepancy problem, a positive result would be the publication of a unified set of data on bilateral transactions. Such cooperation if copied by others should throw light on errors and omissions in the balance of payments on a global basis—a matter of considerable interest and concern.

# Modeling U.S.–Mexico Economic Linkages

By CLARK W. REYNOLDS AND ROBERT K. MCCLEERY\*

The United States and Mexico share a unique history and common border. Despite efforts by both countries to regulate the degree of exchange between them, relentless economic forces give rise to what has been called increasing “silent integration” in recent years. It has become apparent in this and similar cases that trade barriers tend to exacerbate migration, that capital flows in one direction can moderate labor flows in the other, and that limitations on direct investment may lead to even more vulnerable patterns of international indebtedness. These pressures for economic integration operate regardless of policymakers’ preferences, posing a challenge in two separate but related areas of economic analysis. First, by having to look at the mutual interaction of trade and factor flows (including labor, capital, and technology transfers), the analysis of exchange is pushed well beyond its conventional limits to accommodate wage, income, and growth effects in sending and receiving countries. In such a context, normal trade theory appears even more partial and its limitations all the more restrictive. Dynamic links between trade and factor movements and growth and structural change in the respective economies cannot be ignored in cases where initial policy decisions on the part of one country may have a major impact on both, with feedback effects that stretch the limits of intuition.

The second area of analysis challenged by these issues is that of political economy. Here one wishes to assess the costs and benefits to

relevant social groups in both countries of alternative trade, migration, investment, and technology patterns arising from a range of policy options. Such an analysis is complicated not only by the challenges it imposes to the economics of exchange, as mentioned above, but by the fact that in this case the political and social systems of both countries are so different. Partly because of these differences, the flows between them remain highly asymmetrical in terms of benefits, costs, and power relations. Tradeoffs between exchange in goods and services and movements of labor, capital, and technology are further complicated when they contribute to the dynamic pattern of comparative advantage in both countries, as is the case in the United States and Mexico. Moreover the problem increases when both partners face the need for sustained fiscal adjustment, when exchange rates in both countries have been distorted by past policy imperfections, and when the rest of the international economic system is involved in an uncertain path of evolution in production, employment, and technology.

## I. Managing Interdependence

The tension between the benefits from a fuller degree of exchange and the costs perceived by groups on either side of the border leads to a classic political economic problem of managing interdependence. The analysis of interrelated trade, migration, and investment flows in this case cannot only benefit from different but comparable examples elsewhere, such as the integration process among European countries at different levels of development, but can also shed light on ways to model the economic dimensions of policy space open to decision makers. By showing the tradeoffs more clearly, and by assessing their economic impact on different interest groups, the analysis sharpens the range of policy options. There is no attempt in this paper to go beyond a relatively simple

Mellon Foundation, and the Rockefeller Foundation.

dynamic model of exchange between two interdependent economic systems, based on stylized facts drawn from the recent experience of the United States and Mexico. Our simulation model (see our forthcoming working paper) assumes some degree of competition in a capitalist-mixed enterprise system subject to reasonable patterns of accumulation, growth, and employment under five different policy scenarios: (i) the status quo (likely flows based on current migration and investment policies); (ii) much freer movement of labor and capital; (iii) increased labor market controls (Simpson-Mazzoli-type migration policy); and managed interdependence affecting (iv) capital and (v) labor flows. Scenario *v* involves the imposition of a "migration tax" similar to that recommended by the Kindleberger Commission in its OECD report (Charles Kindleberger et al., 1978).

## II. A Migration Tax

There are important differences between the migration tax proposal developed by the Commission and that simulated here, reflecting major dissimilarities between the predominantly legal migration flows in Europe and the undocumented, so-called "black market" labor flows in the North American case. However, the basic purpose of both proposals is similar: to reduce the level of migration, offset some of the cost that migration imposes on social groups in the receiving country, and provide employment-generating transfers to the sending country that will reduce future migration pressures.

The illegal nature of most North American migration leads to a differential in wages of unskilled labor between the two countries that is significantly in excess of the amount required to cover costs of transportation, job search, inherent language and skill differences, and nonmonetary costs of relocation in the United States. We shall call this the "undocumented differential" in wages. Part of this differential reflects economic rents accruing to legal migrants and U.S. workers owing to labor market protection. Part reflects the cost of "coyotes" who smuggle workers across the border. The remainder is the return to those who exercise monopsony

power over undocumented workers. Legalization of migration would eliminate the cost of coyotes, erase exploitation of migrants due to their undocumented status, and reduce the risks associated with migration. Thus the annual level of a "neutral" tax would be equal to those benefits of legalization, which we have roughly estimated as \$2,000. Any specific proposal would, of course, be subject to negotiation based on more refined estimates of the undocumented differential. By the same token, the distribution of tax proceeds between the two countries should also involve binational negotiation, while the split within each country would be a matter of domestic concern.

In the European case, a tax was proposed that would directly reduce the incentive to migrate. A portion of the revenues would be used to encourage those already in the high-wage country to return. In the case of the United States and Mexico, however, the migration tax could be, in effect, a "windfall rents tax" on the benefits of legalization of migration flows. Because the tax would be levied only on the newly legalized migrants, it would leave the initial incentive to migrate and the stock of migrants unchanged. Over time, however, sharing of tax revenues with Mexico can be shown to significantly reduce the incentives of workers to migrate from the supply side.

## III. The Analytical Framework

The approach taken is to apply a simple model of dynamic wave convergence in each one-year period, subject to assumed cost, skill, and preference differentials between the two countries as described above. The conditions that tend toward convergence include relative technological progress and relative increases in the capital-labor ratio (increases in the capital stock and/or decreasing demographic pressures) in the low-wage country, as well as increased exchange between the two countries under reasonably competitive conditions. This can be due to patterns of development in either country or both. In our model, movements of labor, capital, and technology between countries in response to differential rates of return not only decrease these differentials but also affect growth rates

in the respective regions. Increased exchange refers to flows of labor, capital, and technology as well as trade in goods and services. In the formal model, changes in the degree of trade protection are not explicitly introduced, except implicitly through the accommodation of joint production for both markets. Such accommodation will necessarily underlie capital transfers of the magnitude discussed here.

In order to capture some elements of the process of wage convergence (or divergence) we have employed a two-sector model for the United States and Mexico. Each economy has a high-wage, relatively capital-intensive sector and a low-wage sector with relatively low capital intensity. One mechanism of wage convergence is through migration from Mexico's low-wage sector to that of the United States. Another mechanism is through capital flows from the United States to Mexico in response to differential rates of return net of risk, subject to foreign investment barriers. The technology transfer process will be explicitly modeled in our forthcoming version. At present it is handled through exogenous sectoral productivity growth assumptions.

The sectors are defined as follows. The low-wage sector in the United States (*US2*) represents low-skilled labor including personal services, construction workers, and industrial and agricultural laborers. In the base year 1982 this constituted about 10 percent of the U.S. labor force (10 million workers) and represents those workers with which Mexican migrants are in direct competition. The remaining 90 percent is defined as the high-wage sector in the United States (*US1*). The high-wage sector accounted for 92 percent of the capital stock and 95 percent of value-added of the United States. The low-wage sector in Mexico (*MEX2*) represents all primary and tertiary employment (including agriculture and services) constituting 75 percent of the occupied work force (17 million workers) in the base year 1982. The remaining 25 percent is comprised of those in secondary sector (*MEX1*) employment (primarily manufacturing but including oil) which accounts for one-third of both the capital stock and value added.

In our analysis, standard Cobb-Douglas production functions are used to model pro-

duction in each sector. A feature of our model is that gross national income is allowed to differ from gross national product by net factor payments abroad. A wage differential between sectors within each country is maintained by introducing proxies for union power, demand constraints, and a limit on the substitutability of labor for capital which we call a minimum incremental capital-labor ratio. Between the low-wage sectors in Mexico and the United States, the following equilibrium condition holds: wages in *MEX2* are equal to wages in *US2* less the disutility of migrating which comprises the following five variables: cost, preference, skill, discrimination, and tax. Cost is the approximate monetary cost of getting to and across the border and finding a place of employment in the United States. Preference reflects the fact that, holding incomes constant, Mexicans prefer life in Mexico to that of the United States. It is a proxy for family ties, climate, relative price and availability of normally consumed goods and services, and national differences in consumption bundles. The skill variable accounts for differences in education, training, and language capabilities. The discrimination variable accounts for the costs of illegality including the exercise of monopsony power by U.S. employers. The tax variable consists of percentages of best-judgment figures for cost, preference, and discrimination totalling \$2,000, or approximately one-fourth of the real wage differential for unskilled labor between the two countries.

The model works recursively. For a given year, capital is allocated between sectors in each country such that its rate of return is equalized across sectors. Then wages are computed and labor migration takes place in response to absolute real wage differentials between the respective low-wage sectors. In an iterative fashion, capital is subsequently reallocated within each country, and the postmigration labor force is also reallocated between sectors to some extent, reflecting constraints representing labor market segmentation and skill differentials. Wages are recalculated and compared at this new partial equilibrium, and this process is repeated until the wage differential (modified by the cost, preference, skill, discrimination, and in

one case, tax variables) is effectively zero. Then other macroeconomic variables are calculated and recorded, exogenous variables are updated to reflect the passage of another year, and the process begins again for each year from 1983 until 2000.

In the model the exogenous variables for which growth rates are specified are the indigenous supply of labor in Mexico and the United States, as well as pure productivity growth in each sector of the two countries. Given these assumptions, the model is used to simulate the paths of the endogenous variables which include both countries' sectoral and total *GDP*, wage levels, returns to capital, national income, net investment, stock of migrants in the United States, and the allocation of capital and labor between sectors for each of the five scenarios. This permits a range of migration and investment policy options to be studied. There are two interesting sources of feedback: the effect of increases in the rate of return to capital in the United States due to migration or capital transfers on investment in the United States; and, in the migration tax case, the effect of migration on tax revenues, capital stocks, wages, and migration in future periods. We have arbitrarily assumed one specific distribution of the migration tax revenue, 50-50 between the United States and Mexico, and 50-50 between labor and capital within each country. This significantly alleviates both the opportunity cost to U.S. workers of a lower increase in real wages relative to autarky and the cost to capital owners of a lower level of capital income relative to the status quo. In Mexico the disbursement of tax revenues aids both growth (increases in the capital stock) and income distribution (wage subsidies for low-skilled labor).

#### IV. Some Initial Findings

(i) *The Status Quo*: The initial results of our model indicate that the total stock of undocumented Mexican migrants would follow a bell-shaped path over time, rising from an estimated 2.5 million in 1982 to a peak of about 5 million in 1995, associated with *GDP* growth rates of 5.5 and 2.8 percent, respectively, in Mexico and the United States over the entire period through 2000. Between the

two years (1982 and 2000) the absolute wage gap for low-skilled labor between the two countries remains unchanged. In 1982, wage levels averaged \$10,100 and \$1,900, respectively, while at the year 2000, the model estimates them to be \$10,550 and \$2,350, reducing the relative gap slightly from over 5 to 1 to less than 4.5 to 1. All figures given are 1982 U.S. dollars. Real *GDP* rises from \$3,000 billion and \$150 billion in 1982 in the United States and Mexico, respectively, to \$4,940 billion and \$390 billion in the year 2000. (These figures take into consideration the slump in 1982-84, while assuming a fairly steady upward trend thereafter in both countries.) Real wages in the high-skilled sector of the United States and Mexico in 1982 averaged \$24,350 and \$3,680, respectively, rising to \$31,140 and \$6,130 at the end of the period. The relative gap in high-skilled wages declines from 6.6/1 to 5.1/1, a much larger decline than in the case of low-skilled labor. If these trends in migration and wage levels are unacceptable, alternatives to the status quo should be considered. These figures provide the base line against which we present the results of the other scenarios.

(ii) *Free Movement of Labor after 1985*: This scenario is not presented as a realistic policy option, but as a boundary case which sets one limit to the economic dimensions of policy space. Assuming that Mexican workers exhibit a constant preference for living in Mexico and that relocation costs do not rise, the elimination of legal barriers to migration would in this extreme case also produce a bell-shaped curve in the stock of migrants which peaks only after the year 2000. In the first year of legalization, nearly 8 million Mexicans migrate, and the stock reaches the unrealistic level of 16.5 million. Even then there is not full convergence of real wages of unskilled labor which become \$10,460 in the United States and \$3,260 in Mexico. (Of course, long before that point social and political reactions in both countries would have put a lid on the flow that could be far more destabilizing in the long run than the current "black market" in labor flows.)

(iii) *Increased Labor Market Controls*: The Simpson-Mazzoli alternative is simulated with some difficulty, due to ambiguities in just how employer sanctions and increased

border patrol funding translate into our cost variable. First and most importantly, we find that even if Simpson-Mazzoli were to eliminate all undocumented migrants in the first year, the flow may well resume leading to a bell-shaped stock of migrants that would peak in the late 1990's at a level over 1 million more than those legalized at the outset. The process of relative wage convergence would be set back. Simpson-Mazzoli is, of course, only a step toward the other limit of economic policy space, namely autarky (prohibitive barriers to migration). Full autarky would maximize the protection rents to U.S. labor and minimize the degree of convergence through migration. The U.S. wages for unskilled labor would rise by \$40 over the status quo projection while those in Mexico would reach only \$2,200 in the year 2000 compared to the status quo projection of \$2,350, an 8 percent loss. Autarky would also build up pressures for capital to move offshore (though not necessarily to Mexico) with adverse consequences for U.S. wage levels. In the Mexican case, the growth of real wages is sharply reduced. The resources devoted to enforcement of such a restrictive regime would be immense, perhaps exceeding the benefits to workers in the United States, and capital owners in the United States would lose in any event.

(iv) *Managed Interdependence of Capital Flows*: This proposal calls for a significant increase in the amount of co-investment for joint production between the United States and Mexico to eventually serve both markets, with a 50-50 sharing of the proceeds. It is assumed that such investment would neither replace nor stimulate Mexican domestic capital formation, though the latter is likely to result. Migration policy in this scenario is presumed to remain unchanged. The flow of \$5 billion per year between the two countries beginning in 1986 proves to have a significant impact on migration flows, so that the stock of Mexican migrants in the United States peaks in 1985 at 3.5 million (1.5 million below the status quo peak of 5 million in 1995). By the year 2000 this scenario leads to a total stock of migrants of less than 1 million, implying a return flow over the period from 1986 to 2000. Real wages of unskilled labor increase by \$50 in both coun-

tries relative to the status quo scenario, despite a much larger number of workers remaining in Mexico. The capital flow case leads to skilled labor wages which are \$80 higher in the United States and \$150 higher in Mexico than the status quo scenario. Total gross national income in both countries combined is higher than in the status quo case by \$60 billion 1982 dollars in 2000, with the gains split roughly equally. These findings are indicative of the power of managed interdependence in the investment area.

(v) *Managed Interdependence of Labor Flows through a Migration Tax*: The implementation of a tax of \$2,000 would also result in an earlier and lower peak in migration than the status quo, at a stock of about 3 million migrants in 1993. In comparison with the status quo Mexican workers gain, Mexican capitalists gain (the Mexican capital stock grows more rapidly due to the tax and income feedback effects so that the declining return to capital does not slow growth), U.S. capitalists lose slightly as the number of Mexicans in the United States falls below the status quo level, while U.S. workers gain. Combined gross national income of the two countries increases by \$25 billion in the tax case, with a Mexican share of \$16 billion.

In a final scenario the two types of interdependence management, tax and investment policies, are combined. This leads to a fall in the stock of migrants to nearly zero in the year 2000, an increase in joint income of \$70 billion over the status quo in the final year, with the benefits split evenly between the two countries. Real wages of unskilled labor are about \$60 higher in both countries than in the base case, giving a slight improvement for each over the case of investment policy alone.

## V. Conclusions and Implications for Further Analysis

This study illustrates the positive economic impact which Mexico and the United States could receive from some degree of managed interdependence. A migration tax could make use of the gains from "rationalizing" migration policy in a way that compensates workers in the United States for wage gains foregone, significantly reduces the

flow of migrants, and serves to improve income levels and distribution in Mexico. There is an identifiable tradeoff between U.S. investment in Mexico and migration to this country. In our model an annual flow of \$5 billion would reduce the stock of migrants in the United States by 200,000 per year on a cumulative basis. An advantage of the combined tax and investment proposal is that with only 20 percent of the migration that would obtain in the absence of all immigration barriers, 70 percent of the benefits would be achieved in terms of joint income with a more equal binational distribution of the benefits.

In all scenarios, Mexican migration peaks within a generation and in most cases before 1995. These findings strongly support the contention by Mexican sources (F. J. Alejo, 1983) that the migration problem for them is one that is greatest before 1995, as their own economy becomes increasingly able to absorb its own labor, while the supply of new workers decelerates reflecting sharp fertility declines which are already in evidence. The United States, on the other hand, will exhibit increasing demographic complementarities with Mexico as its population ages, requiring more services, even as the proportion of those willing to enter the lower echelons of the labor market declines.

Despite fundamental differences between the U.S.-Mexico case and other experiences,

there are important similarities reflecting what might be called the underlying international development problem. This problem affects all countries, rich and poor. If global political economic stability is to be maintained, the problem must be addressed by policies that serve to manage interdependence in ways which minimize costs and uncertainties and spread benefits as widely as possible within and between countries. For interdependence to be managed at all well, it is useful to engage in some modeling of dynamic economic linkages among countries along with the social and political consequences of alternative policies. Hence the U.S.-Mexico case has potentially wide applicability, perhaps as much in raising relevant questions as in answering them.

# New Developments in Project LINK

By L. R. KLEIN\*

An attempt to model the international transmission mechanism was initiated by project LINK in the summer of 1968. There have been many interim reports on the progress of that effort, over the years, the last major account being some three years old. (See my paper with Peter Pauly and Pascal Voisin, 1982.) It is accordingly appropriate to bring the story up to date.

In the early years of this international cooperative research project, the Bretton Woods system of fixed parities was still alive, but the shift to floating rates presented an immediate research challenge to provide endogenous generation of exchange rates on the basis of meager experience and short data samples. The change in the terms of trade between oil importers and oil exporters provided another challenge, but fortunately the system was constructed from the start with explicit display for energy trade.

Apart from meeting these challenges and coping with the more ordinary changes that are always occurring in the dynamic economy of the real world, the project researchers have always sought to enhance the system. The international model began as a system that was built around trade flows among the leading OECD countries, some thirteen of them. We saw immediately the special problems of model building for developing countries and for centrally planned economies. It was immediately apparent that we would have to include the whole world in the system because the LINK concept was to preserve world accounting identities: world-exports = world imports. These are plural identities because they must hold by commodity groups and in both real and nominal terms. We resolved the issue by programming the computations in a specific way so that each country's exports = weighted sum

of partners' imports and import prices = weighted sum of partners' export prices.

The global *consistency* conditions were achieved in the LINK system by programming techniques that have been explained in detail in previous project summaries. Over the years, other international model-building projects have been implemented in various government agencies, multinational agencies, research consulting enterprises and some universities. There is now a whole corps of international models; some emphasizing trade, some emphasizing financial flows, and some emphasizing partial interrelationships.

A feature of the LINK system, however, has been its emphasis on the principle that each resident model builder knows his or her own country (area) best. LINK, therefore, remains as a cooperative venture, with participants from model-building centers round the world. Models are maintained for separate use at home but also sent to LINK central under certain specifications for consistency at linkage points, and world-consistent simulations are made for the project as a whole. The cooperating researchers meet, face-to-face, twice yearly.

## I. New Developments

With the help of United Nations staff, models for developing countries were introduced into the LINK system at a very early stage. They included area models for Africa, Asia—South East and Pacific—Latin America, and the Middle East. These models emphasized trade, domestic accumulation of fixed capital, and internal spending. The UN staff also provided models for the centrally planned economies. From Wharton Econometrics, the project drew on the model of the Soviet Union that was developed independently of the LINK effort. Also, a model of the Peoples' Republic of China was developed specifically for LINK by Lawrence Lau of Stanford University, who was an early participant in the entire project.

\*Department of Economics, University of Pennsylvania, Philadelphia, PA 19104.

Over the years more countries were added to the LINK system. Now, virtually every OECD country is participating directly (with the exceptions of Iceland, Portugal, Turkey, Yugoslavia). To this expanded grouping of industrial countries, we are now able to include models for individual developing countries (with some small residual area groupings), which together with OECD and centrally planned economic (CPE) models, make up a system of 72 separate component models. These models are all interrelated through a commodity-specific trade matrix that is fully  $72 \times 72$ . This unusual statistical construct for trade has been prepared by the UN staff. At the earlier stage, the four area models of the developing countries were related to the rest of the system by only one row-column pair in the trade matrix. That limitation has now been broken, and the feedback interrelationships cover 72 entities at a completely bilateral level. It is, understandably, a mammoth job of information management and computing. The system now has about 16,000 simultaneous equations.

At the present level of disaggregation, there are still some unwanted groupings and the next stage of refinement will probably cover 80 separate models, with some major African countries being given separate treatment. To give a rough idea of the present scope of the system, the LINK project calculations produce some summary tables of key macroeconomic statistics for individual models, together with some broad groupings. These are taken from the present (December 1984) baseline projection, and are but an aggregative sample of the full system's results.

In order to facilitate the work of adding some 35 new models for developing countries on fairly short notice, we built similar (not identical) systems in Philadelphia, but several representatives from developing countries participate regularly in LINK, and we shall soon have fresh models maintained in a few specific developing countries as part of the system. These countries are Chile, Nigeria, Venezuela, Taiwan, South Korea, the Philippines, India, and Pakistan.

It is worthy of note that two models for centrally planned economies will be maintained on site, namely, Poland (University of Lodz) and Hungary (International Market

Research Institute). It is hoped that a model of the Peoples' Republic of China will be built domestically for use in LINK.

The inclusion of developing country models in LINK, with prominent display, has long been a distant goal, but with the emergence of specific problems for developing countries, their extended treatment became a priority of the first order. It has long been expected that developed countries would have a more modest economic growth prospect in the 1970's and in the years to come in the 1980's, than previously, especially the buoyant years of 1950-73. This indicates trouble for the developing countries, whose growth prospects depend heavily on performance in the developed countries. In addition, the appearance of the LDC debt problem, in bold relief after summer 1982, made their explicit study mandatory, in order to assess the chance of their being able to manage their economies without default or other crisis-precipitating events. There is significant feedback from developing to developed countries, and this is one of the objectives of investigation in the new enlarged system.

The models prepared for the developing countries have both a general and a specific group of structural equations. The general equations are those for various types of final demand, including exporting and importing. They also cover the generating of factor-income flows, prices, and wage rates. Specific aspects of these models vary from country to country. They show such things as

- 1) particular export markets for primary and other (service) products (coffee for Brazil, metals for Chile and Peru, grain for Argentina, overseas construction for Korea, Persian Gulf earnings for many poor countries, Suez revenues for Egypt, etc.);

- 2) sensitivity of money supply to external and to internal deficits; and

- 3) dependence of production on imports of raw materials and capital equipment.

When heavily indebted developing countries found themselves unable to service debt in the usual way, they cut back imports severely. This had adverse effects on the United States and other industrial countries. This feedback effect is one of the targets for research explanation in this phase of LINK

activity, but also the cutback in imports caused serious production declines in the developing countries that initiated the import reductions.

In most models for industrial countries, the import multipliers are negative. This is a standard Keynesian result, but for developing countries, their model structure should be different in that imports should vary *directly* with overall production. We saw extreme cases of this in Brazil and Mexico during 1982-83.

With these thoughts, models were specifically designed for developing countries that would deal effectively with such issues. At present, there are 35 LDC models in an extended LINK system. Scenario, multiplier, sensitivity and forecast work will bring out flaws in these models, and after a year or two, we shall be having a strong system on a very large scale of country coverage.

These LDC models were designed at LINK Central (University of Pennsylvania) using a great deal of insight and guidance from third-world scholars who have participated in LINK meetings for several years. They are from Nigeria, Venezuela, Chile, Taiwan, South Korea, India, and Pakistan. The project also received much help from staff economists of the UN and Asian Development Bank. Shinichi Ichimura of Kyoto University also contributed greatly to this development, on the basis of his studies of a sublinkage system in the Pacific Basin.

Gradually the focus of model responsibility will shift from LINK Central to particular economists in each of several developing countries. We are already installing models from some of the developing countries listed above. These models come from ongoing econometric practice in the particular countries, and their work will continue indefinitely into the future.

Related to the work on model building for developing countries in LINK, we are returning to an older theme, namely, the integration of commodity models with country models in the system. These enable us to study pricing and export earnings of primary producing countries many of whom are LDCs.

Additional studies of exchange rate determination, but not from the standpoint of

capital flows, were reported to the 1983 meeting of LINK at the Bank of Japan, Tokyo. Endogenous treatment of exchange rates will continue to be a lively area of study within LINK.

At the time of the freeing-up of exchange rates in the floating system, a problem was posed in LINK research as follows:

For fixed parities trade balances are endogenous, exchange rates are exogenous; and

For equilibrium rates under floating parities, trade balances (or current accounts) are set at exogenous target levels, exchange rates are estimated as endogenous instrument variables.

This makes exchange rate determination a problem of the well-known target and instrument formulation for economic policy formation in the manner of Tinbergen. This particular problem was formulated as one of equal numbers of instruments and targets. This attractive way of looking at the problem intrigued Keith Johnson of the LINK staff in 1974, and he studied the matter in his dissertation research. To solve this problem, he modified the LINK system into a much simpler model, with an identical master specification for each country. He solved the large-scale computational problem with the reduced system.

Christian Petersen and Peter Pauly of the present LINK staff reached a milestone in 1984 research by successfully programming the solution to this problem in a much expanded LINK system, ten years later. Their solution is very general and can be used for unequal numbers of targets and instruments as well as for the case of equality. The latter is strategic, however, because the loss function in the general case will be zero; therefore, this is a point that is straightforward for checking the enormously complicated computing problem. Petersen and Pauly were able to program the case of equality between numbers of instruments and targets for implementation of Ronald McKinnon's proposals for monetary stabilization by stabilizing exchange rates at purchasing power parity levels. These results were presented to a special LINK session held at the Federal Reserve Bank of San Francisco, August 1984, and will be reported in a volume of proceedings that is now being edited.

LINK researchers were able to solve the very difficult computing problem of optimal economic policy formation in the context of the multimodel system. In a broader sense, the whole computational apparatus of LINK has been much improved. It is more efficient, faster, cheaper, and more user friendly (with training). It is operated mainly on an interactive level from remote terminals now. Yet, it is still a lengthy calculation, taking about 20–30 minutes for a world simulation of about five-years horizon.

The new computer software for LINK was used to good advantage in a telecommunications experiment. The topic of the experiment was coordination of economic policy across country boundaries. Teams of LINK participants were asked to make live criticism of a basic LINK forecast, with a policy scenario of changed American choices between fiscal expansion and monetary restraint.

A team of European participants in LINK were assembled in a studio of British Telecom in London, facing a similar team of North Americans and a Japanese representative at SBS studios in McClean, Virginia. These two groups were in touch via satellite in an audio-visual mode. Two ("blind") groups with audio service alone were assembled at Los Angeles on the North American side, and at Geneva on the other side.

In a conventional audio-visual hookup, a general discussion can be held, looking at the other side's expressions while they hold forth. We added a new feature, namely audio-visual linkage together with a computer fully in the picture. After discussing the baseline forecast and the amendments, country-by-country, we interpreted for the model's computer inputs the quantitative meaning of the changes. The new information generated by the audio-visual exchange thus became the foundation for implementing a computer assisted response. It took nearly 20 minutes to execute a solution response to the changes in monetary and fiscal policies. The result appeared, finally, on computer screens that could be seen by all participants from both major teams in London and McClean. The computer screens with scenario information were also available to the participants in Geneva and in Los Angeles.

This calculation was something of a bottleneck, but we used the time fairly well in commenting about the whole projection, and when the final results were available on all screens simultaneously we were able to have a further teleconference discussion about the meaning of the findings.

LINK has shown how the power of the computer, working with a central data file, can be incorporated into an audio-visual exercise. This is what we wanted to show, in addition to analysis of the substantive issues at stake. We were able to show how government technicians, international civil servants, and interested academics can be in frequent touch for discussing projections or in working out new ones. The whole experiment lasted four hours.

The computing got completed for the telecommunications experiment, but it took a long time, using up much valuable satellite space for four hours. This suggests that new approaches to computing that could significantly reduce the time required for our standard scenarios, would greatly benefit the use of telecommunications methods. A goal should be the execution of a LINK response to verbal proposals in less than 5 minutes. Once that goal is met, it will be much easier and less expensive to use teleconferencing for coordinating economic policy.

New advances in computer method are entirely possible. The next step is to consider the *supercomputer*, which is obviously a hardware configuration that would deal with the inherent problems of simulating big systems, like the present augmented LINK model, and also serving to manage its large data files. But it is not bigness alone that suggests the supercomputer for the LINK problem. Speed is of the essence as indicated by the limitations of the computer associated teleconferencing exercise just discussed. The supercomputer does offer the possibility of significantly reducing the time required for lengthy simulations with the large LINK model for some 72 countries and areas. There is, however, one further aspect of natural fit between the LINK system and the architecture of the latest supercomputer. Some work by the principle of parallel processing, that is, multiple computer processing units are lined up, perhaps around a ring or lined up

along some other convenient configuration. The main point, however, is that the processors should be working simultaneously, doing computations all at once. The fit with the LINK system is that individual country models would not be solved purely serially, but would be solved simultaneously on the different processors, one per country. They would then all be sent to a linkage processor. In principle, this approach holds out great promise and is on our present research agenda.

Research analysis of the potentialities of the supercomputer is promising. It follows a "hardware" line of improvement. A "software" is also being explored through analysis of algorithmic efficiency. Work on a predecessor project of LINK, namely, the Brookings-SSRC model project for the U.S. economy fully established the Gauss-Seidel algorithm for simulating large scale systems. At the time (mid-1960's) large scale meant some 300 equations. Now we are dealing with thousands of simultaneous equations, and attention is being paid to the use of Newton's method for algorithmic efficiency. Newton's method was, in fact, investigated in connection with the development of simulation algorithms for the Brookings-SSRC model but abandoned in favor of the Gauss-Seidel method, which proved to be faster, cheaper, and easier to handle. The multi-model, in particular, appears to offer some natural advantages to Newton's method, and LINK computing research is now following that direction for improving the speed, cost, and efficiency of our present research work.

Related to the research investigations of the supercomputer, we are exploring another approach for parallel processing but not on the supercomputer hardware system. In collaboration with Noah Prywes of Pennsyl-

vania's Moore School of Electrical Engineering, LINK is exploring *cooperative processing*, that is, solving large-scale dynamic systems for simulation purposes, where the individual models are solved "at home" on whatever hardware is available with results being sent electronically to LINK central for consolidating consistently into a world model. People cooperating in highly dispersed centers represent a high degree of research collaboration and can probably achieve results that are similar to those produced by a supercomputer. A key factor in the use of cooperative computing is the ability to transmit data regularly, efficiently, and accurately to the central LINK files in Philadelphia. From our side, it would relieve a substantial amount of processing at LINK Central. With high-quality fellow workers, this aspect of the industry, in far-flung areas of the world, can be the highest form of collaborative effort in our subject.

## II. Conclusion

From the discussion of this paper, it can be seen that the system and practices of project LINK are far from being statically conceived. It is a dynamic and live project, exploring new ways for handling analyses of the developing countries, capital flows, exchange rates movements, teleconferencing with computers, and new ways to compute standard LINK tabulations more efficiently, more quickly, and more accurately.

IN HONOR OF STEPHEN H. HYMER: THE FIRST QUARTER CENTURY  
OF THE THEORY OF FOREIGN DIRECT INVESTMENT†

The Influence of Hymer's Dissertation on the  
Theory of Foreign Direct Investment

By JOHN H. DUNNING AND ALAN M. RUGMAN\*

The great contribution of Stephen Hymer's seminal dissertation (1960) was to escape from the intellectual straightjacket of neo-classical-type trade and financial theory, and move us towards an analysis of the multinational enterprise (*MNE*) based upon industrial organization theory. The magnitude of this breakthrough can be put into perspective by considering the state of the art when Hymer wrote twenty-five years ago.

In 1960 the prevailing explanation of international capital movements relied exclusively upon a neoclassical financial theory of portfolio flows. In this frictionless world of perfect competition, with no transaction costs, capital moves in response to changes in interest rate (or profit) differentials (see Carl Iversen, 1936). According to this arbitrage theory, capital is assumed to be transacted between independent buyers and sellers, that is, there is no role for the *MNE*. At the time there was no separate theory of foreign direct investment (*FDI*). The work did not even ask the question, of "Why is there *FDI*?", despite the evidence of sectoral cross investments and the existence of large *MNEs* with intra-industry trade. If anything, the early work on *FDI* focused upon the "where" of investment in a particular nation or industry, for example, Dunning (1958) was chiefly interested in explaining U.S. *FDI*

in Britain. There was little interest in understanding the reasons for the *MNE*, or the nature of its operations.

The pioneering conceptual insight of Hymer was to break out of the arid mold of international trade and investment theory and focus attention upon the *MNE* per se. This permits us to treat *FDI* as a modality by which firms extend their territorial horizons abroad. The unique feature of *FDI* is a mechanism by which the *MNE* maintains control over productive activities outside its national boundaries, that is, *FDI* means international production. In this view, *FDI* is more than a process by which assets or claims are exchanged internationally (see Robert Aliber, 1970; 1983). Hymer's great insight was in focusing attention upon the *MNE* as the institution for international production, rather than international exchange.

Until Hymer articulated the process of *FDI* as an international extension of industrial organization theory, it was not possible to understand why the *MNE* transfers intermediate products such as knowledge or technology among its units across different nations while still retaining property rights over such assets. Today it is widely recognized that the theory of *FDI* (i.e., international production) is primarily about the transfer of nonfinancial and ownership-specific intangible assets by the *MNE*, which needs to appropriate and control the rate of use of its internalized advantage(s), see Rugman (1981), David Teece (1981; 1982), Richard Caves (1982) and Mark Casson (1983).

In this paper we first acknowledge Hymer's contribution to the theory of *FDI* and then move on to reinterpret his dissertation in the light of the modern theory of the *MNE*. We

†*Discussants*: Raymond Vernon, Harvard University; Robert Z. Aliber, University of Chicago; Paul Streeten, Boston University.

\*Professor of Economics, University of Reading, RG6 2AA England, and Director of the Centre for International Business Studies, Dalhousie University, Halifax Nova Scotia, B3H 1Z5 Canada, respectively.

find that Hymer's dissertation is remarkably prescient in its identification of structural market failure, but that it somewhat overlooks the transaction-cost side of the literature. This led Hymer to overemphasize the market-power advantages of *MNEs*, while his followers have misinterpreted the need for regulation of the *MNE* based on this predilection. We find that some parts of Hymer's dissertation provide useful linkages to the relatively new work on strategic management of *MNEs* in a world of global competitive rivalry.

### I. Structural or Transaction-Cost Market Imperfections?

The major value of Hymer's dissertation is its clear statement in chapters 1 and 2 of the industrial organization explanation of *FDI*. Here Hymer explains that the *MNE* is a creature of market imperfections. The *MNE* has the ability to use its international operations to separate markets and remove competition, or to exploit an advantage. Control over the use of assets transferred abroad is required by the *MNE* in order to minimize risks and to achieve monopolistic power. Hymer (1976) states that control of a foreign subsidiary "is desired in order to remove competition between that foreign enterprise and enterprises in other countries... or to appropriate fully the returns on certain skills and abilities" (p. 25). Later he states that the *MNE* "is a practical institutional device which substitutes for the market. The firm internalizes or supersedes the market" (p. 48).

Unfortunately, Hymer misses the distinction between structural and transaction-cost (cognitive) market imperfections made, for example, by Dunning (1981, p. 29). Hymer's entire analysis is based upon structural imperfections, which are Bain-type advantages to enhance the asset power of the *MNE*. They include scale economies, knowledge advantages, distribution networks, product diversification, and credit advantages. All of these help the *MNE* to close markets and thereby increase its market power. Hymer cites Joe Bain (1956) extensively for his analysis of structural market imperfections. On the other hand, cognitive imperfections are

Williamson-type transaction costs (see Oliver Williamson, 1975). These transaction costs arise naturally, or at least are assumed to be exogenous to the *MNE*. The *MNE* then responds to the transaction costs by creating an internal market. The latter type of market imperfections are inadequately treated by Hymer.

Once internalization has been achieved, the *MNE* experiences an ownership advantage which appears to be similar to a Bain-type asset power advantage. However, it is always important to distinguish the source of the advantage. If an exogenous market imperfection leads the *MNE* to organize an internal market as a substitute for either a missing regular (external) market, for example, in the pricing of knowledge, or to replace more expensive modes of transactions, then the process of internalization improves efficiency. No rents would be expected for the *MNE* when it is exercising transaction-cost power. In contrast, Hymer's concept of the *MNE* is restricted to the structural market imperfections view. He sees the *MNE* as having the power to close markets by using one or more of the Bain-type advantages. In turn, he believes that this leads to the generation of rents for the *MNE*.

It would seem to us that Hymer did not fully appreciate the work of Ronald Coase (1937) when he wrote in 1960. A close reading of Hymer's dissertation reveals an exclusive emphasis upon the structural market imperfections viewpoint, plus a discussion of the role of the tariff as an instrument inducing *FDI* instead of exporting as a mode of entry. No discussion of the Coasian theory of the firm can be found in Hymer. Despite the attempt of Charles Kindleberger (1984) to reinterpret Hymer's passing mention of information costs, it is clear that Hymer does not discuss them as transaction costs. It appears that Hymer did not embrace the full meaning and implications of market failure, and that his analysis, while not faulty, is limited to only part of the field of industrial organization. For a similar interpretation, see Teece (1981) and Casson in Rugman (1982).

In his dissertation, especially in chapter 3 in his discussion of *FDI* vs. licensing, Hymer does allude to "market impurities," which the casual reader might interpret as meaning

transaction costs. However, in these sections Hymer is again thinking of structural market imperfections, especially the alleged ability of *MNEs* to enjoy monopolistic benefits by closing markets. Hymer compares internalization to "contractual collusion," via cartels and other agreements between firms. He refers to Dunning's description of the tobacco industry in the early years of this century as an example of worldwide market sharing activities (p. 89). Yet at no point in the dissertation does Hymer explicitly or implicitly consider that hierarchical organizational structures can replace imperfect markets for reasons of efficiency. To Hymer, *MNEs* always exist for monopolistic reasons, that is, "to separate markets and prevent competition between units..." (p. 67).

Hymer also pays little attention to the location of *MNE* activity which is an important cog in the eclectic theory of international production (see Dunning, 1981). By this omission, Hymer neglects the importance of the geographical and spatial dimension of the *MNE* and the manner in which location-specific factors are determined interdependently with ownership- (firm-) specific factors in the process of *FDI*. The reader of Hymer does not get the message that internalization of transactions by the *MNE* is required in order to capture the externalities of separately related but commonly owned activities.

## II. Efficiency and Strategic Management

An interesting linkage of Hymer's asset power viewpoint can be made to the modern literature in strategic management. Michael Porter (1980) and others have suggested that the art of strategic management is to identify entry and exit barriers, and then operate generic strategies based upon price competition, product differentiation, or the seeking of market niches for product lines of the firm. Clearly these entry and exit barriers are virtually identical to the Bain-type advantages of which Hymer was so fond. What does this imply? Is Hymer the grandfather of strategic management as well as of the theory of the *MNE*? Probably not, but he should receive credit for directing attention towards

the ability of *MNEs* to close markets by the use of strategies which are now the basic tools of business management policy.

Hymer's view of the *MNE* as an institution exercising asset power spills over into some of his later, more radical, work where he writes about the collusive nature of monopoly capital (see the collection of his major papers in Hymer, 1979). This strand of his thinking is reflected in the dissertation, although much less strongly than in his later works. It was probably a result of Hymer's exposure to the U.S. economic environment of the 1950's, where there was a strong anti-trust literature. Since then the field of industrial organization has achieved greater maturity, and it is unlikely that Hymer's naive views of international oligopoly and collusive activity are consistent with modern thinking in the field, especially that summarized by Williamson (1981) in his discussion of bounded rationality, opportunism, and asset specificity.

As an example consider Hymer's treatment of vertical integration, which he perceives to be a monopoly device for providing extra profits. He misses the point of modern strategic management where vertical integration can be used as a competitive weapon against nonintegrated firms, to reduce costs or increase revenues. The great advantage of being an *MNE* is the ability to use internal markets across nations. The *MNE* can use transfer prices, maneuver liquid assets, move around production facilities, and so on. In this way the *MNE* has greater degrees of freedom than a uni-national firm confined to one country. Yet, as an offset, the *MNE* faces environmental uncertainty as foreign governments can change the political, cultural, and social factors which determine its economic efficiency.

The essence of this dispute about whether or not *MNEs* are efficient stems from the manner in which the *MNE* is modeled, especially the nature of the assumptions made about the endogeneity or exogeneity of the market imperfections. If the market imperfections are natural transaction costs, then the *MNE* is operating against nature and so internalization is conceptually efficient. However, if the market imperfections are

structural and endogenized, leading to asset power, then the *MNE* is best viewed as operating strategically, and such actions may or may not be efficient.

### III. Dynamics and Diversification

There are two other areas of theoretical interest in Hymer's dissertation. The first is his emphasis upon market structure and the dynamic nature of the ownership-specific advantages of *MNEs*. This is consistent with the dynamic modeling of Raymond Vernon (1966) and his doctoral students working upon product life cycles and the oligopolistic reaction of *MNEs*. Today, we recognize that the asset power of the *MNE* is threatened by rival *MNEs* who launch new product lines incorporating new technology or other types of firm-specific advantages. Again the compatibility of Hymer's work with the field of strategic management is acknowledged by this emphasis upon the changing nature and dynamic evolution of firm-specific advantages.

The second area of interest is Hymer's insight into the advantages of international diversification. He states "that profits in one country may be negatively correlated with profits of another country..." (p. 94), and that "an investor may be able to achieve greater stability in his profits by diversifying his portfolio and investing part in each country. This investment may be undertaken by shareholders of the firm, and not the firm itself..." (p. 95). In this section, Hymer foresees the later literature on the role of the *MNE* as an indirect vehicle for the achievement of the gains from international diversification in a world where individuals face transaction costs in undertaking such diversification themselves (see Rugman, 1979). This, in itself, was a considerable intuitive achievement of Hymer's, since twenty-five years ago the modern theory of finance was not yet developed. The mean-variance framework was not well understood and asset pricing models were not yet developed. It is ironic that the recent literature in international finance has ignored Hymer's correct insight in this area, while the literature on the regulation of *MNEs* has built upon his

somewhat flawed analysis of market imperfections.

### IV. Hymer and Policy

Hymer's dissertation does not deal with policy and he has little to say about the political or social issues of developing nations. He does not attempt to calculate the benefits and costs of *FDI* or technology transfer, nor does he analyze explicitly the impact of *MNEs* on developing nations. Despite his reputation as a radical economist, fully justified by his later work, Hymer's dissertation itself follows conventional lines. It is written broadly within the framework of mainstream economic principles of the time and it does not use *dependencia* arguments.

However, by his emphasis upon the market-closing ability of the *MNE*, Hymer shifted the emphasis from strictly efficiency-type evaluations of *FDI* towards the more sensitive issues of distribution of income and social justice. In this way Hymer's dissertation provides hints about the later development of his work in which he switched completely from the neoclassical efficiency paradigm to a radical critique of economics in which Marxist questions of distribution are at the forefront of his analysis.

Due to the theoretical impossibility of reconciling efficiency and equity arguments, a great debate has ensued over the last twenty-five years about the conflicting objectives of *MNEs* and nation states. Hymer's focus upon the ability of *MNEs* to limit markets and thereby increase their ability to earn rents helped to give an apparently plausible basis to this debate. His work has been interpreted by critics of the *MNEs* as a rationale for regulation of *MNEs*. This interpretation of Hymer's work is simplistic at best and, given his neglect of the transactional side of the theory of the *MNE*, is liable to be misleading.

What we have learned in the last twenty-five years is that the conflicts between the *MNEs* and nation states are infinitely more subtle than can be resolved by the partial nature of Hymer's dissertation work. These issues need to be analyzed today using models of disequilibrium dynamics. The older

static welfare criterion for evaluating the contribution of institutions, such as the MNE, to resource allocation has lost its appeal. In a disequilibrium situation it is not always apparent that the activities of MNEs lead to a more (or less) efficient allocation of resources. The answer depends upon an evaluation (often on a case-by-case basis) of their relative use of asset power in closing markets and of their ability to respond to transaction costs inefficiencies. To this unresolved debate the 1960 dissertation by Hymer still brings fresh insights, but fewer unambiguous policy implications than his followers have imagined.

# Multinational Enterprise, Internal Governance, and Industrial Organization

By DAVID J. TEECE\*

A multinational enterprise (*MNE*) is a firm that controls and manages production establishments located in at least two countries. In a Coasian sense, *MNEs* substitute for the market. They can be divided into two nonmutually exclusive types. One turns out essentially the same line of goods or services from each facility in several different locations, and will henceforth be referred to as horizontally integrated *MNEs*. The other produces outputs in some facilities which serve as inputs into other facilities located across national boundaries. These are vertically integrated *MNEs*.

Two conceptually distinct issues exist which need to be addressed in order to explain the *MNE*.<sup>1</sup> The first is the locational question of why production occurs where it does. The second is why certain production activities occur under the control of foreign enterprises while others do not. The locational issues are explained rather well by the standard theories of comparative costs. The control (internalization) issues cannot be explained by standard theory, yet these are central to a theory of the *MNE* as compared to a theory of international production. The former is concerned with explaining the nationality of the firms engaging in international production, while the latter simply explains the international distribution of the world's productive activities without concern for ownership and control patterns.

\*Professor of Business Administration, University of California, Berkeley, CA 94720. I thank Robert Aliber, Greg Hawkins, and Jim Wilcox for helpful comments.

<sup>1</sup>John Dunning (1981) develops a useful taxonomy which explains *MNEs* in terms of ownership (of rent-yielding assets), locational, and internalization advantages. For expositional reasons, I collapse what Dunning refers to as ownership factors into locational factors because it is the coupling of the two which explains where production ought to be located.

Until about two decades ago, economists viewed the *MNE* as simply an arbitrageur of capital, transferring equity capital from countries where returns were low to those where it was higher, earning the arbitrageurs rents and contributing to efficient resource allocation. The capital arbitrage theory of *MNE* predicted that *MNEs* would be headquartered in countries where the domestic marginal productivity of capital was relatively low, from which they will transfer capital to subsidiaries where the marginal productivity was higher.

As Stephen Hymer (1976) first observed, however, there are several features of direct foreign investment (*DFI*) and *MNE* which are inconsistent with this theory. The *MNEs* overwhelmingly finance their host-country operations in host-country capital markets. Furthermore, there are substantial cross flows of direct foreign investment (see Jean-Francois Hennart, 1982), as well as substantial concentration of *DFI* and *MNEs* in particular industries. These observations would be consistent with an arbitrage theory only if domestic capital markets were highly balkanized.

Despite the contrary evidence, Robert Aliber (1970, 1983) has reiterated a version of the capital arbitrage theory based on the identification of separable currency areas. The argument goes approximately as follows: there are substantial differences among countries in nominal and real interest rates. Because nominal interest rate differentials are poor forecasts of future changes in exchange rates, a wedge is introduced between returns on similar securities denominated in different currencies.

If portfolio managers had "perfectly" priced exchange risk, then the corporate managers would be reluctant to have their firms incur foreign exchange

risks...the parents of the subsidiaries take on the foreign exchange exposure because the corporate managers believe that the interest rate differentials are significantly larger than from the anticipated rate of change of the exchange rate...The expansion of firms across national borders is consistent with the view that corporate managers internalize the costs and risks of foreign exchange exposures at lower costs than portfolio investors.

[Aliber, 1983, p. 252]

The argument is flimsy and incomplete at best. No explanation of why corporate managers can internalize exchange rate risk at lower costs than portfolio managers is provided or even suggested. Moreover, as mentioned earlier, only a small part of direct foreign investment involves intercompany loans from parents to subsidiaries. Aliber claims otherwise but cites no evidence.<sup>2</sup>

In searching for a plausible theory of *DFI*, Hymer advanced two major tenets. One was that *DFI* was motivated by attempts to remove competition among enterprises in different countries, and the other was the *DFI* was motivated by domestic firms' attempts to increase the returns from the utilization of firms' special advantages (Hymer, 1976, p. 33). With respect to the second category, Hymer drew on Joe Bain (1956) to suggest that the source of the advantage could be in superior production techniques, imperfections in input markets which allow lower buying prices for established firms, and similar first-mover advantages. Possessing such special advantages, a national firm could be profitable outside the home country despite its relative ignorance of local conditions abroad. It would prefer to do so rather than

license in order to avoid possible bilateral monopoly situations, to enforce use restriction which could not be imposed contractually, to avoid the haggling between licensor and licensee associated with the evaluation of the value of the technology, and to better protect its advantage from the perils of misappropriation.

These were powerful insights, which laid the foundation for a completely new paradigm of the international firm. In one short thesis, Hymer transported the theory of direct foreign investment out of international trade and finance and into industrial organization. But the field of industrial organization circa 1960 did not have quite the richness it has today, and the library of concepts from which Hymer could borrow was especially sparse with respect to the economics of complex organizations.

Furthermore, Hymer was constrained by the absence of a clear welfare criteria for evaluating the *MNE*. In the absence of alternatives, Hymer seized upon perfect competition and Pareto optimality and inevitably arrived at troublesome conclusions. This is because he saw the *raison d'être* of the *MNE* as stemming from the "impurities of the market [that] would not arise in competitive industries" (1976, p. 86), which led him to the conclusion that "a restriction on direct investment or a policy to break up multinational corporations may be in some cases the only way of establishing a higher degree of competition in that industry...the underdeveloped countries need to devote an important share of their scarce resources to building up national enterprises..." (Hymer, 1970, p. 444). However, if the *MNE* is based on a special advantage, as Hymer claims, then the conclusion of this line of logic is that the special cost advantage should be abandoned in order to worship at the altar of perfect competition.

There is no doubt that Hymer's work represents a major contribution to the positive economics of the international firm. However, his thesis is misleading in its emphasis upon market power rather than efficiency, as is explained below. Relatedly, it does not provide a workable framework for assessing host-country control issues. The framework

<sup>2</sup>The Aliber theory may have some validity with respect to shifts in the total levels of foreign investment at the national level. Even here, "safe haven" and economic-growth considerations also appear to be important. The recent drop in direct foreign investment in the United States—\$7.0 billion in 1983, \$10.8 billion in 1982, 23.2 billion in 1981, 12.2 billion in 1980, and \$15.3 billion in 1979—certainly doesn't square well with the theory.

advanced is also static, and unable to grapple with intermediate organizational forms, such as cooperative and teaming agreements.

### **I. Monopoly vs. Efficiency Interpretations of the Multinational Enterprise**

As I have indicated elsewhere (1981, 1983), the essence of the multinational firm varies according to whether its investment abroad is primarily vertical or horizontal. The rationale for vertical direct investment stems from the efficient functioning of internal production and distribution systems when bilateral dependence with attendant strategic maneuvering and costly haggling might otherwise emerge (Oliver Williamson, 1975; myself, 1977, 1983; K. Monteverde and myself, 1982). By substituting an internal governance structure (i.e., vertical integration) capable of circumventing such problems, the multinational firm makes a substantial contribution to economic efficiency. Vertical integration permits specialized cost-saving equipment to be installed in both upstream and downstream locations with less risk that it will be idled by international disputes between enterprises of different nationality facing different incentives. Vertical direct foreign investment ought to be seen primarily as a response to market failure, and its explanation does not require appeal to classical market power considerations. Indeed, except under restrictive assumptions, vertical integration cannot be employed as a mechanism to extract monopoly or monopsony rents. Hymer avoids separate treatment of vertical direct foreign investment, but hints that sequential monopoly may be at its heart, blind to the spurious nature of leverage theories of vertical integration. In any event, Hymer appears unaware of the organizational efficiencies which can be associated with vertical integration, and misinterpreted the welfare implication of the *MNE* on this account.

The explanation of horizontal direct foreign investment requires the coupling of two requirements. One is that the firm possess a rent-yielding asset of some kind (for example, know-how) which warrants utilization in offshore production facilities, and the second

is that market transactions (know-how, licensing arrangements) are inferior to direct foreign investment as instruments for appropriating rents from the sale of the services of the asset in foreign markets. This is because of both the revenue-enhancing and cost-saving properties of the *MNE*. Direct foreign investment will be selected where contractual difficulties such as the ability to price know-how, or to write, execute, and enforce use restrictions governing technology transfer arrangements are anticipated. The intra-organizational mode for transferring technology is not only revenue enhancing but also cost saving, as empirical studies have demonstrated (my 1977 article). Hymer tacitly recognized these cost-saving aspects of horizontal direct foreign investment (1976, p. 50) and explicitly recognized its revenue-enhancing properties, which he chose to emphasize, bluntly stating that "monopoly problems pervade any discussion of international operations and direct investment" (1976, pp. 85–86). In a technical sense, Hymer was correct, in that in the presence of perfect competition and frictionless markets, the incentives for direct foreign investment disappear. However, applied welfare economists are unlikely to view any departure from perfect competition with alarm. What is needed, and what was not supplied by Hymer, was an assessment of the comparative welfare properties of multinational firms and the market alternatives. Hymer's comparisons of the *MNE* with the frictionless market fiction was inapposite and fueled host-country antagonism towards the *MNE*.

Hymer's thesis has stimulated a flurry of books and articles on the multinational firm, including P. J. Buckley and Mark Casson (1976) and Alan Rugman (1982). As Charles Kindleberger (1984, pp. 180–81) points out, there isn't all that much in this literature that cannot be found in Hymer. What is accomplished, however, is a reemphasis away from market power concerns and towards the economies associated with internalization, a literature which is derived from Williamson (1975). Departures from perfect competition in product markets and transactional advantages from internalization are needed to explain horizontal *DFI*, but Hymer chooses

only to emphasize and develop the former. The new literature therefore provides a much-needed balance.<sup>3</sup> The principal deficiency is that the internalization arguments are insufficiently micro analytic, failing to establish a structure which can discriminate between situations where direct foreign investment is more efficient than alternative organizational modes. Clearly, direct foreign investment isn't the most efficient mode of organization in all circumstances where a firm possesses an advantage which is the foundation of a business opportunity abroad. The contingent framework which is needed to create a theory of the *MNE* is sketched in my papers (1981, 1983), where it is shown that the incentives to use nonmarket modes for horizontal transactions swing upon the degree to which the technology in question cannot be evaluated, packaged, and protected using contractual instruments. In the case of vertical transactions, the presence of transaction-specific assets generating *ex post* "lock in" conditions is the key incentive driving foreign direct investment. Needless to say, these conditions don't exist all the time, and arm's length contracts will often suffice.

## II. Host-Country Controls

The transaction cost theory embedded in the above explanation of the *MNE* also contains some interesting policy conclusions. Besides maintaining that the *MNE* ought mainly to be regarded in economizing terms, the micro-analytic lens afforded by transaction-cost economics enables one to assess, from an efficiency perspective, the desirability of host countries exercising special controls over the activities of *MNEs*.

The need for special governance over the *MNE* depends in large measure on whether

the host country provides transaction-specific assets to support the *MNE*. This might be the case, for instance, if the host country dedicates roads and electric utilities to support a particular *MNE*, or if workers develop special skills to meet the needs of an *MNE* affiliate. When specialized assets are developed for the foreign firm, they cannot be redeployed easily should the *MNE* decide to pull out, or to otherwise adjust its plans opportunistically. The host country has incentives to develop investment safeguards in these circumstances. These can take many forms, including some type of penalty for early withdrawal or delayed expansion, or the creation of specialized governance structures for resolving disputes between the *MNE* and the host country. Alternatively, the *MNE* could be asked to post a bond, engaging in what Williamson (1983) refers to as the exchange of hostages. Despite safeguards of the type indicated, additional benefits might accrue from information disclosure involving relevant strategic plans, or informational representation on the Board of Directors, as this might enable the host country and workers with firm-specific skills to anticipate future developments and plan accordingly. Failure to design such governance structures may result in host countries failing to provide the necessary infrastructure. It bears repeating, however, that special governance or regulatory machinery is not needed unless the host country is deploying specialized assets to support the foreign firm.

The argument is also symmetrical and more empirically relevant when viewed from the *MNE's* perspective. If *MNEs* are to invest specialized assets dedicated to the host country, immobile plant and equipment being a case in point, investment safeguards are needed. An expropriation price agreed upon *ex ante* which the *MNE* can trigger at its discretion, somewhat analogous to certain types of severance pay in employment contracts, is one such possibility. Arbitration is another. Failure to design machinery of this kind will dissuade direct foreign investment when specialized nonredeployable assets are needed for efficient production. Alternatively, the *MNE* will extract a "fee" to offset this risk. The fee might take the form of

<sup>3</sup> It is noteworthy, however, that subsequent work in the spirit of Hymer, such as Richard Caves (1971), chose to emphasize the monopoly issues and neglected the internalization issues which are mentioned in Hymer but not well developed. Caves (1982) has subsequently redressed this misemphasis and signed on to the transaction cost thesis.

higher prices for goods sold in the host country, and/or lower prices for commodities purchased.

### III. Dynamic Considerations

The literature on the *MNE*, whether emphasizing market power or efficiency, suffers from a common deficiency: underemphasis on dynamics. The historical evidence shows American and British *MNEs* transitioning to offshore production after first establishing a sales branch abroad which in turn commonly preceded the establishment of contractual relationship with a foreign sales agent (Steven Nicholas, 1983). Agency contracts were unsatisfactory, containing vague and difficult to enforce performance clauses. Attempts to shore these up by specifying, quantitatively, budgets for traveling, advertising, engineering support, and the like, as well as certain inventory levels on the agents' premises proved unsatisfactory. The transition from agency to branch sales office was facilitated by the manufacturer's gradual accumulation of information about the foreign market, acquired through monitoring its foreign agents, and by expansion in sales volumes to levels which would support a facility of minimum economic size. The establishment of a sales branch also demonstrated to customers a more solid commitment on the part of the manufacturer to support the market in question. Often triggered by the failure or termination of an agent, the establishment of a foreign sales subsidiary subsequently became the platform upon which a manufacturing investment was made (Alfred Chandler, 1977, p. 369). However, the transition to manufacturing depended upon the relationship of production costs abroad to production costs at home plus tariffs and transportation, as well as governance considerations. Nevertheless, as Yair Aharoni (1966) points out, the direct investment process is governed by more than just economic incentives. An initiating force, galvanizing the organization into action, is often needed. The presence of a sales office also assists information collection, thereby significantly lowering perceptions of uncertainty, and raising the probability that a firm will engage

in direct foreign investment if the underlying cost conditions permit it. Clearly, transaction-cost economics must be married to organizational decision theory if the dynamics of channel selection are to be better understood.

### IV. Conclusion

The Hymer thesis cast the *MNE* and direct investment in a new light. The contribution was considerable, though the analysis was incomplete, and the welfare conclusions misleading. Considerable progress has been made in the last two decades in embellishing the theory and correcting the errors. More work needs to be done in understanding the distinctive characteristics of the *MNE*, its internal governance structure, and its incentive limits. Progress in this area is unlikely to be rapid until our understanding of the internal resource allocation and governance processes within firms begins to match our understanding of how these processes work in markets.

# Hymer and Public Policy in *LDCs*

By DONALD J. LECRAW\*

Initially this paper was titled, "Stephen Hymer's Influence on Public Policy in *LDCs*." In an attempt to research this impossible subject, I conducted a citation search in the SSCI. The SSCI listed 442 citations in 192 different journals over the period 1977 to 1983, a count that places Hymer in the top five writers on international business and the multinational enterprise over that period. His writings were cited in journals devoted to law, history, philosophy, sociology, psychology, political science, geography, business, anthropology, broadcasting, peace research, statistics, migration, and urban, regional, agricultural, trade, financial, labor, industrial, and development economics; they were cited in journals devoted to the study of Africa, Asia, Latin America, as well as Europe, Australia, New Zealand, and North America; and they were cited by authors across the spectrum from arch conservative to radical political economists. The breadth of discipline, geography, and viewpoint of the authors who found Hymer's writings useful in their analysis reflects Hymer's multidisciplinary approach to problems, the originality of his insights, the clarity of his thought, and the forcefulness of his writing.

Although Hymer is best known for his work on the multinational enterprise (*MNE*), he also was intensely concerned with problems of less developed countries (*LDCs*) and the public policies they might use to alleviate the problems arising from trade and foreign direct investment (*FDI*). In his analyses, Hymer started from his base in economics, especially the economics of the *MNE*, but also used the insights of historical, political, and sociological analysis to illuminate these complex subjects. In using this approach Hymer may have fallen between two camps in

the analysis of public policy issues in *LDCs*: the "pure" economists (who have often viewed him as a bright, but misguided and ultimately fallen angel) on the one side, and the radical political economists (who have viewed him as a rising, if somewhat backward star) on the other side. Instead of bridging the gap, Hymer may have fallen into it: his insights cited, but his conclusions discounted as faulty or half-formed. This is unfortunate, since Hymer, writing in the 1960's and early 1970's, speaks directly to many of the concerns of today and of the future: the New International Economic Order, the North-South dialogue, and the basic needs of those at the bottom of the income distribution in high-income and low-income countries alike.

Hymer's writings addressed two major questions: how best should a small, developing country interact with the world economy through trade, inward (and outward) *FDI*, and technology licensing? How best should such a country organize its internal economic activity to meet the needs of all its people, especially those in the lower two-thirds of the income distribution?

To understand Hymer's approach to the analysis of these two questions and his contribution to public policy in *LDCs*, it is useful to set them within the context of his background, education and experience. Hymer was a Canadian. He grew up and received his first university degree in Canada, a country with a small, open economy, which largely exports raw materials and imports manufactured products, and whose manufacturing, energy, and mining sectors are dominated by subsidiaries of *MNEs*. In many ways, Canada was (and is) akin to the *LDCs* and his interests naturally turned in their direction. He was educated as an industrial organization economist at McGill and MIT. His experience and education, therefore, gave him a knowledge of large, multinational enterprises and the tools to analyze them. After MIT, Hymer worked in Ghana where he saw

\*Professor, School of Business Administration, University of Western Ontario, London, Ontario, N6A 3K7 Canada. I am grateful for partial funding from the Centre for International Business Studies and the Fund for Excellence, U.W.O.

the harsh effects of poverty in the aftermath of colonial imperialism and the neocolonial economic system of trade and the *MNE*. He soon concluded, however, that economics by itself was not a useful tool of analysis of the problems in *LDCs*—as he wrote: “Both in my study on Ghana and my study of direct foreign investment the disproportion between the questions I was asking and the tools I had to deal with them grew daily” (1979, p. 277).

Hymer returned to teach at Yale during the time of the “Greening of America,” when many were questioning both the value of the fruits of capitalist economic development and the costs of the political, social, and military system with which it was linked. In Canada, where Hymer worked with the Task Force on the Structure of the Canadian Economy in the late 1960’s, one of the forms of this revolt was a rise in economic nationalism which questioned the benefits and costs of Canada’s close links with (some called them the yoke of) the United States through trade, technology, and *MNEs*. The conclusions of this Task Force Report eventually led to the formation of FIRA (the Foreign Investment Review Agency) and Canada’s following the “Third Option” to attempt to diversify its trade away from the United States.

It is difficult to summarize and characterize Hymer’s conclusions for public policy in *LDCs*, since his method of analysis and conclusions changed and developed so substantially over his life. Yet it is also incorrect to concentrate on his later papers, since several of his early papers (see Hymer and Stephen Resnick, 1969) are among the most often cited in the literature. With this brief background, we can turn to the two fundamental questions for Hymer and public policy in *LDCs*.

### I. The Implications of an Open Economy for *LDCs*

Throughout his writings, Hymer recognized that international trade and *FDI* had the potential to increase world economic efficiency and accelerate the economic development of *LDCs* through the international market system.

The multinational corporations...will probably spread production more evenly over the world’s surface... [and] be a force for diffusing industrialization to the less developed countries....

[1971b, p. 119]

...[A]n industrial program which fails to open up the national market and indeed provides shoddy goods to substitute for goods previously imported from abroad can bring about a retreat [to inefficient production] and away from specialization and exchange. ...From the point of view of government policy, two important targets are a dynamic industrial sector...are a communications and transport system to facilitate the flow of goods, capital, and labor among all the trading partners....

[Hymer-Resnick, 1969, p. 505]

The question of income distribution both among and within countries was central to Hymer’s writings. While recognizing the potential benefits of trade and foreign direct investment, Hymer concluded that the institutional structure through which they were conducted led to a disproportionate share of the benefits being realized by high-income countries (and by small groups within those countries) and a disproportionate share of the costs being realized by low-income ones. His early industrial organization analysis of the *MNE* led him to the conclusion that firms engaged in *FDI* to preserve and extend their oligopoly power. In his thesis, Hymer (1976) concluded that in addition to the (small) efficiency loss in resource allocation arising from oligopolistic pricing by *MNEs* above the competitive price (arguably offset by the dynamic innovations of *MNEs*), the transfer rectangle from consumers to producers could accrue to stakeholders in the *MNE* located abroad. In addition, the *MNE* had the ability to reduce the host country’s participation in its supranormal profits through manipulation of transfer prices on international intrafirm transfers of goods, services, capital and technology. Similarly for the gains from international trade, Hymer and Resnick concluded: “Much of the

gains from export growth went to the government, to urban centers, and to local and foreign elites" (1970, p. 485).

Beyond these problems of the distribution of the benefits of an open economy, Hymer identified several other economic problems arising from international involvement: inappropriate products (which developed and catered to "wants" rather than to "needs"); inappropriate production technology; concentration and urbanization of economic activity; and labor force dislocation and the wasting of human capital (through "slash and burn" strategies of financial capital mobility).

In his early writings, Hymer raised the possibility that these economic costs to an open economy from international trade, capital, *FDI*, and licensing could be reduced by government regulation at the national and multinational level. This possibility was squarely in the tradition of Hymer's schooling of reformist government intervention. Ultimately, however, he concluded that these instruments of public policy would be largely ineffective against the power of *MNEs*, and the governments and segments of society that benefited from them and supported them. Such government intervention might increase the benefits flowing to *LDCs*, but not to the point at which the net economic, social and political benefits would be positive.

This negative outcome of international economic interaction was due to the unequal distribution of *power*—both economic power and political power—between the groups competing for the benefits generated by an open world economy. Hymer saw the *MNE* (and the international economy under the regime of the *MNE*) as organized in a complex pyramid of power, information, activity, and wealth. At the top of the pyramid were the head offices of *MNEs* located in a few metropolitan centers in high-income countries. From these heights, the *MNE* planned and controlled worldwide operations in *R&D*, production, and marketing. Below them in the hierarchy lay the coordinators located in regional centers in the home country and abroad. At the lowest level lay the specialized functional levels of production and distribution located in the countries of

the periphery. By this organizational structure, *MNEs* could reap the benefits of both decentralization and centralization, differentiation in production and marketing, and integration in coordination, planning and control. It also allowed *MNEs* to draw the surplus generated by their operations in trade and investment toward the top of the pyramid. At the same time it isolated the units (host-nation states and labor) at the bottom to render them powerless to seize the benefits of international exchange for themselves individually or to unite to achieve their goals as a group. "There is a close correspondence between the centralization of control within the corporation and the centralization of control within the international economy. The multinational corporation system thus does not seem to offer the world either national independence or equality" (Hymer, 1971c, pp. 8–9).

Similarly, Hymer concluded: "international trade... is often based on a division between superior and subordinate rather than a division between equals" (1971d, p. 12).

Even if the countries of the periphery could gain the information, expertise, determination, and power to deal with *MNEs* and to shift the balance of international trade toward their favor, the governments of the high-income countries, the homes of the *MNEs*, would intervene in their role as protectors and champions of the existing economic structure in general and *MNEs* in particular: "In the last analysis, markets come out of the barrel of a gun, and to establish an integrated world economy on capitalist lines requires the international mobilization of political power" (Hymer, 1972, p. 93).

Given these economic, organizational, and political realities, Hymer concluded that public policy in *LDCs* should be directed toward disengagement from the international system of trade and foreign direct investment both by blocking trade and *FDI*, and by heavily regulating them. By these actions, *LDCs* could develop to suit the basic needs of their people. Under this development path, *LDCs* "would have little need for multinational corporations" (Hymer, 1972, p. 105) and "some withdrawal from international

trade was necessary to make the life made possible by science pleasant and worthwhile" (Hymer, 1971d, p. 19).

## II. International Structure of Economic Activity

Given Hymer's public policy prescriptions that *LDCs* should distance themselves from the international economy, his second major question is how they should organize their internal economies to best accomplish this goal.

On this question, Hymer's views changed most radically and completely. In an early article (1971a), Hymer concluded that in Ghana both the British colonial administration and the Nkrumah socialist government impeded economic development and reduced future development potential by actively discriminating against the entrepreneurial class: the British with an aim of perpetuating empire and the post-independence government in order to channel economic activity through the state. Hymer concluded that in the future public policy would: "Hopefully not place much value on the development planning from *above* that has characterized most of Ghana's experience up until now" (1971a, p. 178).

Hymer soon changed his positive conclusions on the efficacy of using the entrepreneurial class in *LDCs* as the primary engine for development. He based this conclusion on three propositions. First, as described above, the international economic system in general and *MNEs* in particular are antithetical to development in *LDCs*. Second, the entrepreneurial (capitalist) class in *LDCs* are likely to be co-opted to join with *MNEs* in their exploitation of *LDCs* since "...in the last analysis their [the native capitalist class] interest lies with the international system" (1979, p. 259).

Third, even if the national capitalist class tried to act in the national interest, they "are very weak and in no way a match for international capital" (1979, p. 259) and would soon be bought out or forced out of business.

Since "national capital" cannot be relied upon to protect and foster national development, the best and, in fact, the only real alternative is "state capital":

The counterstrategy for the underdeveloped country is national planning. It seems to me that only such an organization could be efficient in mobilizing the strengths of the population as a whole in the interest of the population as a whole. [1979, p. 255]

The primary goal of such a development policy would be to provide minimum standards of health, education and food and clothing for the entire population. [1971c, p. 11]

Hymer (1979) concluded that national socialist planning would have several advantages: it would centralize national decision making at one point; allow scope for planning economies of scale; subordinate economic decisions to political and social ones; increase a nation's bargaining power, expertise, and information base in dealing with the international economy; create a polycentric system to facilitate international nation to nation interaction; and decrease the distinction between the periphery and the center of the world economy. Such a system, if implemented soon, might also be able to take advantage of the temporary breakdown in the *MNE* oligopolistic consensus and open conflicts between *MNEs* brought about by the emergence of European and Japanese *MNEs*.

Hymer recognizes that there might be economic costs to such a development policy, but: "the high productivity of the new technology allows countries greater scope for national independence, since it becomes far less urgent to economize on scarce resources" (Hymer and Robert Rowthorn, 1970, p. 87). There may also be political costs to such a system, but: "Problems of ensuring democracy within a region would remain, but they would seem to be more tractable than ones associated with world stratification by multinational corporations" (1979, p. 255).

## III. Summary

Hymer's writings on public policy in *LDCs* focused on one set of questions: "The question is not so much whether industry will grow rapidly, but who will organize it—na-

tional capital, state capital, or foreign capital" (1979, p. 250).

Hymer concluded that development via the use of socialist state capital was the only means by which LDCs could foster growth to benefit all their population since foreign capital and foreign trade with high-income countries lead to inequality and subjugation: "underdevelopment is created by the same process as development and forms, as it were, the ugly underbelly of affluence" (Hymer and Resnick, 1969-70, p. 191). To reverse this pattern of inequality it is necessary for LDCs: "...to build a system that will reflect as closely as possible what the heart of the people demands, we need a world economy where information can move freely between nations but capital, that is, power cannot" (Hymer, 1979, p. 255).

#### IV. Retrospective

Since so many of Hymer's writings were devoted to what will be and what should be in the long run, perhaps ten to fifteen years is not time enough for a fair assessment of the accuracy of his conclusions. Nonetheless, at least in the short run, it would be fair to say that, in general, things are not progressing along the path Hymer envisioned or desired.

The United States has disengaged in Vietnam and the major instances of overt imperialist aggression against LDCs are the victorious Vietnamese in Cambodia and Laos, and the Russians in Afghanistan. Trade unions, one possible counterbalance to the power of MNEs, are less of a political and economic force than ten years ago, with the exception of the Solidarity Trade Union in Poland, a socialist country. Following the example of Japan, LDCs led by Singapore, Hong Kong, Taiwan, and Korea have embarked on a more outward-looking trade and investment development strategy. Even China and India are beginning to look outward in trade and FDI. The oligopolistic consensus between MNEs from the United States, Europe, and Japan foretold by Hymer has not as yet materialized (in fact, competition has increased) despite increased interpenetration of home-country markets through FDI and

joint ventures. The MNEs and export-oriented national firms based in LDCs have grown in number, size, and power as LDCs have gained increased access to technology, capital and expertise in international business.

Yet, despite these developments, the LDCs as a group are now more, not less, dependent and subservient to high-income capitalist countries. Hymer correctly analyzed the current problems of LDC debt and trade protectionism:

...[T]hese countries [the LDCs] find that the major creditor countries compete vigorously in offering suppliers credit but form a united front when collecting debt. [1979, p. 247]

It is not clear that the West has the economic agents to...open up marketing channels for the underdeveloped world...or the ability to readjust its own structure of production to allow importation of goods from the periphery.

[Hymer-Resnick, 1969-70, p. 190]

It is unfortunate that Hymer is not here to help LDCs formulate public policy in response to these problems.

As a last ironic note, Canada, which so influenced Hymer's ideas, has turned away, at least for the present, from the path of nationalism and socialism he advocated: FIRA has been disbanded; the third option is dead; and free trade with the United States is being actively discussed by a new conservative government.

# HUMAN CAPITAL AND CULTURE: ANALYSES OF VARIATIONS IN LABOR MARKET PERFORMANCE<sup>†</sup>

## Religion and the Earnings Function

By NIGEL TOMES\*

Economics is fundamentally atheistic. Religious beliefs, practices, and behavior play no role in the life of homo economicus. Recently, however, there has been some interest in earnings differentials between religious groups. There are a number of motivations for this research. First, the analysis of earnings differentials by religion extends the analysis of intergroup differences beyond the narrow focus on black-white and male-female differences, to groups where differences in ability associated with religious, ethnic, or cultural factors may be of considerable importance. Second, religion may be an important dimension of family background and environment—family values, skills, endowments, goals and culture inherited or acquired during childhood—which influence earnings, the rate of return to human capital, and the intergenerational transmission of economic status.

This paper summarizes recent theoretical models and empirical research regarding the influence of religion on earnings and the rate of return to human capital. Empirical results from the 1981 Canadian Census are also reported.

### I. Theoretical Perspectives

The intergenerational transmission of religious affiliation appears substantial. Over 80 percent of adult U.S. males, belonging to a major religious group (Protestant/Catholic/Jewish)

claimed affiliation with the religion in which they were raised (see my 1984 article, Table 2). The institution of the family appears therefore to perform a central role in determining religious behavior.

Gary Becker and I (1979) provide a theoretical framework for analyzing the intergenerational transmission of economic status and other characteristics in which children are assumed to receive endowments determined by the reputation and "connections" of their families, the genetic constitutions of parents, and the learning, skills, and goals acquired through belonging to a particular family culture. Such endowments are potentially important determinants of human capital investments and the rate of return on such investments. Religious affiliation represents one measurable dimension of family endowments and culture.

More generally the formative years in the family can be viewed as producing not only human capital, but also "religious capital"—including ethical and moral codes of behavior governing consumption, the allocation of time and interpersonal relationships. Religious capital and human capital may interact, both in the accumulation process and in utilization. Greater ability or human capital may increase the capacity to learn and retain religious tenets. The role of Protestant Sunday School in the rise of literacy is consistent with such complementarity (Lee Soltow and Edward Stevens, 1981). Complementarity in production would lead families with higher desired stocks of religious capital to make greater investments in human capital, due to its additional benefits in the religious sphere. Other things equal, greater investments would result in lower returns to human capital.

Religious capital and human capital may also interact in the marketplace. Investing in

<sup>†</sup>*Discussants:* Barry Chiswick, University of Illinois-Chicago; Stephen Steinberg, Queens College, CUNY.

\*University of Western Ontario, London, Ontario N6A 5C2 Canada, and Economics Research Center/NORC.

religious capital may involve the acquisition of traits such as honesty, diligence, and reliability, that are compensated in the labor market and may affect the returns to human capital. Monitoring and sanctions by group members may ensure greater adherence to these tenets among members than by other individuals, creating incentives among employers to use religion as a signal for productive characteristics. Religious beliefs may prohibit or proscribe certain skills, occupations, and working practices (for example, the rejection by the Amish of modern technology). Such restrictions appear likely to lower earnings by reducing the choice set of religious adherents. Whether the returns to human capital are increased or reduced depends on such factors as whether prohibited occupations are human capital intensive.

One hypothesis regarding the interaction between religion and the return to human capital concerns the earnings of Jews. The argument, formalized by Reuven Brenner and Nicholas Kiefer (1981), is that because of their past cultural history of the expropriation of material wealth, Jews make greater investments in human capital, which is embodied and transportable, and receive a lower rate of return. In contrast, Becker has conjectured that the high incomes and achievements of Jews are explained by high marginal returns on human capital investments.

Religious affiliation that influences earnings and human capital investments should also affect other dimensions of family choice. In particular "quality-quantity" models emphasize that parental investments in children and fertility are jointly determined (see Becker's and my article, 1976). Thus high returns to the human capital of Jews may explain their low fertility levels. Conversely, religious tenets regarding fertility should also influence parental investments. Thus, if Roman Catholics face additional psychic costs of birth control, and this lowers the price of numbers of children, the resulting larger family size would tend to reduce investments in each child and raise the marginal returns on such investments.

Finally, there are other channels through which religion may influence earnings. Religious sanctions on divorce may increase the

expected duration of marriage and hence encourage greater specialization and division of labor between spouses raising the labor market skills and earnings of one spouse. Moreover, religious institutions may help resolve intergenerational conflicts regarding parental investments in children and reciprocal reimbursement and support of the elderly. However, so far, these possibilities have not been examined in the literature.

## II. Empirical Studies

Sociologists have devoted some attention to income differentials by religion. The finding that Jews receive higher incomes than non-Jews, controlling for a variety of characteristics, appears almost universal. The ranking of Catholics and Protestants has been more controversial. Andrew Greeley (1976), in particular, has argued forcefully that Catholics earn more than similar Protestants and are members of the American economic elite in terms of income. Other researchers report no significant difference. However, most of these studies analyze income rather than earnings and constrain the effects of religion to be additive, so that the returns to human capital are not permitted to vary across religious groups.

Recent studies by economists employ the human capital framework. Barry Chiswick (1983) examined the earnings of Jewish males using the 1970 U.S. Census. In the absence of information on religion, Chiswick identifies Jews as individuals with a Yiddish or Hebrew mother tongue, restricting his attention to second-generation Americans. Compared with non-Jews, Jewish men have 16 percent higher earnings (other things the same), a 20 percent higher rate of return to schooling (0.081 vs. 0.068) and a steeper experience-earnings profile—suggesting that American Jews are more productive in creating and using human capital. These results represent evidence against the hypothesis that the investment portfolio of Jews is "biased" towards human capital, since this implies a lower return to the human capital of Jews.

My article (1983) analyzes earnings differences by religion using the 1971 Canadian Census that contains information on reli-

gious affiliation and hence permits the direct identification of Jews. The estimated returns to Jews from schooling and experience exceed those of other non-Jews, and in a number of cases these differences are statistically significant. Given the small number of Jews in the sample, these findings buttress Chiswick's conclusion that Jews receive higher rate of return on human capital. By way of contrast, the payoff to Jews from a university degree, holding years of schooling constant (the "credential effect"), is less than to other groups, and does not differ significantly from zero.

Comparing other religious groups in Canada, the returns to Protestants from schooling, experience, and a university degree exceed those to Roman Catholics. The coefficients imply considerable differences across religious groups in the lifetime earnings (human wealth). Ronald Meng and Jim Sentance (1984) find that these differences persist when the usual measures of family background are included. The observation that Catholics make smaller investments than Protestants and receive a lower rate of return is inconsistent with the hypothesis that these differences are a reflection of divergent fertility behavior. Rather, differences in abilities, school quality, and other factors may result in lower returns to human capital to Catholic families.

My recent study (1984) analyzes the interaction of religion and earnings using U.S. survey data—the NORC General Social Survey. One advantage of these data is that they identify the religion in which an individual was raised—a measure that is clearly preferable in terms of exogeneity. When religious differences are constrained to be additive, apart from a Jewish differential, there is virtually no evidence that religious background affects earnings. This contrasts with Greeley's claims of a sizeable Catholic advantage, based on analysis of the same data. The explanation appears to lie in the use of family income rather than earnings and the limited set of regressors employed in Greeley's study. In separate earnings regressions the marginal returns to Catholics from college education exceed those to similar Protestants (see my article, 1984, Table 4).

This offsets the disadvantage to Catholics of lower precollege returns. Hence the largest Protestant-Catholic differential (about 18 percent) occurs amongst high school graduates who do not enter college. This differential narrows at higher levels of schooling and implies that the secular growth in education will narrow the earnings differential between major religious groups.

### III. Further Results

Tables 1 and 2 present additional results based on the 1981 Canadian Census. The sample consists of native-born males age 25–64 who worked in 1980. The empirical human capital specification is similar to that employed in my article (1983) (see also Notes to Table 1). In Table 1, the effects of religious affiliation are constrained to be additive—only the intercepts are permitted to differ across religious groups. The reference group is Protestants. There are two possible ways of identifying Jews—either by ethnic background or current religious affiliation. Not surprisingly these measures are highly correlated: 0.92. The coefficients reported in line 1 imply that, other things equal, Ethnic Jews earn 12.7 percent more than Protestants, while the residual group (no religion/other religion) earn 5.1 percent less than Protestants. Both these differences are highly significant. There is no Catholic-Protestant differential. If Jews are identified by religion (line 2), the Jewish advantage declines to 10.2 percent. When both Jewish ethnicity and religion are included, only the ethnic variable achieves significance (line 3).

The results reported in lines 1–3 may reflect the different spatial location of religious groups. Jews in particular are highly urbanized: 95 percent live in the 13 largest cities; 70 percent in the two largest cities: Toronto and Montreal. When the sample is restricted to the large cities (line 4), the Jewish differential declines to 7.25 percent—equivalent to the payoff from 1.8 years of schooling. The earnings disadvantage to the residual group increases slightly to 6 percent.

The final two lines of Table 1 divide the sample between Quebec and the rest of Canada, since Quebec differs linguistically,

TABLE 1—EARNINGS FUNCTIONS FOR RELIGIOUS GROUPS IN CANADA, 1980: ADDITIVE EFFECTS

Sample	Ethnic Jews	Religious Jews	Roman Catholics	No Religion /Other Religion
1) All Canada	0.120 (4.946)	—	0.004 (0.624)	−0.052 (6.787)
2) All Canada	—	0.097 (3.983)	0.005 (0.628)	−0.052 (6.813)
3) All Canada	0.155 (2.613)	−0.037 (0.640)	0.004 (0.593)	−0.052 (6.813)
4) 14 Cities	0.070 (2.943)	—	−0.010 (0.983)	−0.061 (5.868)
5) Canada excl. Quebec	0.107 (3.553)	—	−0.004 (0.522)	−0.051 (6.184)
6) Quebec	0.177 (4.110)	—	0.047 (2.032)	−0.070 (2.300)

Notes: Sample: Canadian-born males age 25–64 (inclusive), ethnic origin not Chinese or black, with positive weeks worked in 1980 and positive earnings (from employment plus self-employment), not in the armed forces and able to speak one of the official languages ( $N = 80,986$ : 1 percent Jews, 39 percent Protestants, and 47 percent Catholics).

Dependent variable: natural log of earnings (1980).

Other variables in the regression (coefficients not reported): Years of schooling, experience and its square, log of weeks worked, dummy variables for: language, provincial and urban location, ethnic origin, university degree, self-employment, government employment, and not married, intercept.

Coefficients are reported on dummy variables for religion. Reference group is Protestant: Anglican, Baptist, Lutheran, Mennonite, Pentecostal, Presbyterian or United Church (combined Methodist and Congregational).

Absolute value of  $t$ -statistics are shown in parentheses.

culturally, and perhaps economically from the rest of Canada. Earnings differentials by religion appear larger in Québec: Ethnic Jews earn 19.4 percent more, Catholics 4.8 percent more, and the residual group 6.8 percent less than Protestants.

Table 2 reports the coefficients on human capital variables when separate regressions are estimated for major religious groups. In terms of the returns to schooling there are two groups: Ethnic Jews and Protestants receive a rate of return of 4.4 percent (lines 1–2), while Catholics and the residual group receive returns of 3.4 percent (lines 3–4). However the schooling coefficient for Jews does not differ significantly from that of other groups. More generally, there is very

TABLE 2—EARNINGS FUNCTIONS FOR RELIGIOUS GROUPS: SELECTED COEFFICIENTS

Sample	Years of Schooling	Experience	University Degree
A. All of Canada			
1) Ethnic Jews	0.043 (3.485)	0.047 (5.800)	0.250 (2.920)
2) Protestants	0.044 (27.513)	0.037 (26.840)	0.158 (10.667)

C. Canada excl. Quebec			
9) Ethnic Jews	0.058 (3.798)	0.054 (5.327)	0.175 (1.663)
10) Protestants	0.043 (26.656)	0.036 (25.844)	0.159 (10.497)
11) Roman Catholics	0.034 (15.132)	0.030 (15.985)	0.154 (7.072)
12) No Religion/ Other Religion	0.034 (11.114)	0.039 (15.381)	0.155 (5.957)
D. Quebec			
13) Ethnic Jews	0.008 (0.387)	0.039 (2.700)	0.417 (2.836)
14) Protestants	0.059 (6.897)	0.048 (6.338)	0.148 (1.883)
15) Roman Catholics	0.033 (21.480)	0.037 (26.878)	0.272 (17.272)
16) No Religion/ Other Religion	0.038 (3.641)	0.051 (6.072)	0.255 (3.266)

Notes: See Table 1.

little evidence that the returns to Jews from human capital (schooling and experience) exceed those to other groups. The only instance of a significant Jewish differential is for Canada excluding Quebec where the experience coefficient for Jews exceeds that of Catholics (line 9 vs. 11).

Taken as a whole this is meager evidence that the returns to Jews from human capital exceed those of other groups. These Jewish-non-Jewish differentials are considerably smaller than those reported in my earlier article (1983) using comparable 1970 data.

This suggests that more recent Jewish cohorts are becoming assimilated into the mainstream of economic Canadian life. By 1980 possession of a university degree was as important for Jews as for other religious groups. This was not the case in 1970.

In contrast, the Catholic-Protestant differentials in returns to schooling and experience persisted through the 1970's. In each of the samples the rate of return to Protestants from schooling significantly exceeds that to Catholics. Moreover, the payoff to experience for Protestants exceeds that to Catholics in samples B and C. However, in contrast to the results for 1970, the payoffs to Catholics from a university degree in 1980 exceed those to Protestants. A closer examination reveals that this difference arises mainly in Quebec.

Because of the larger payoffs to Catholics from a university degree, the Protestant-Catholic differential does not change monotonically with the level of education. The difference in degree coefficients in lines 2 and 3 roughly compensates for the difference in schooling coefficients, so that four years of university with a degree yields the same earnings increment for both Protestants and Catholics. Put differently, the difference in the returns to schooling occurs mainly at the pre-university level.

Thus far empirical research on religion and earnings has focused exclusively on males. By ignoring women workers we neglect an increasingly important segment of the labor force and overlook the possibility that the sexual division of labor may differ significantly between religious groups. Preliminary results from the 1981 Canadian Census indicate that religious earnings differences among women are strikingly different than among men.<sup>1</sup> Using data on all working women, when coefficients are constrained to be equal, ethnic Jews earn 8.8 percent less ( $t = 2.77$ ) and Roman Catholics earn 3.4 percent more ( $t = 3.39$ ) than the Protestant reference group. Thus while Jewish males earn significantly *more*, their female

counterparts earn *less* than the Protestant reference group. We would expect these differentials to be associated with contrasting sexual divisions of labor with Jewish males more specialized and Catholic males less specialized in the labor market compared to Protestants. The converse patterns should apply to women. The pattern for the returns to schooling among women is also different: 0.026 ( $t = 1.245$ ) for ethnic Jews; 0.057 ( $t = 23.84$ ) for Protestants; and 0.061 ( $t = 30.68$ ) for Catholics. The returns to Jews do not exceed those of other groups, nor do the returns to Protestants exceed those to Catholics. In fact, none of the coefficient differences are significant.

#### IV. Conclusions

The returns to research by economists on religion and earnings have been small. One problem is that the lack of robust stylized facts leads to the rejection of most simple hypotheses. Earlier studies found that Jews receive higher returns to human capital, but not in recent Canadian data. In Canada, human capital returns to Protestants exceed those to Catholics in both 1970 and 1980 data, but this result does not generalize to the United States. One empirical generalization that seems to apply is that, other things equal, Jewish males earn more than other religious-ethnic groups. The results presented here suggest that the converse is true for females. Perhaps one hypothesis worth pursuing is that cultural and ethnic values lead to a much greater sexual division of labor in Jewish families. This may lead Jewish parents to invest differently in sons vs. daughters.

# Cultural Differences in Labor Force Participation Among Married Women

By CORDELIA W. REIMERS\*

Both the distribution of income and the role of ethnicity in economic behavior can be illuminated by an analysis of ethnic differences in married women's labor supply. Differences in wives' labor supply are the main source, beside differences in rates of female headship and wages, of the disparities in family income among racial and ethnic groups in the United States (see my 1984 article). Moreover, differences among ethnic subcultures may affect the labor supply of wives more than they influence many other types of economic behavior. Ethnic groups are distinguished by, among other things, views about male and female roles in the family and about wives and mothers working outside the home, as well as by the value placed on children, family size, household composition, and the education of women. These "cultural" differences may give rise to systematic differences in utility functions that lead to systematic differences in behavior by women in different ethnic or nativity groups who face the same constraints or opportunity set. Such cultural differences in utility functions no doubt are historically shaped by economic as well as other circumstances, and they evolve, but more slowly than the economic conditions. Ethnic differences in attitudes are, therefore, presumably more pronounced in the first generation of immigrants than in their American-born descendants.

These cultural attitudes may have both direct and indirect effects on wives' labor supply. They directly affect the allocation of time between home and market work by women with the *same* education, number of

children, etc. They also affect decisions about education, fertility, and other choices which in turn influence the market work opportunities and value of home time, and so indirectly affect labor force participation.

Virtually all of the numerous studies of black-white differences in female labor supply have found that black wives have higher labor force participation rates (*LFPR*) than whites, even after adjusting for differences in measured variables such as age, children, education, location, other family income, and wages. (For a summary of the results, see Mark Killingsworth, 1983, pp. 122, 195, 202, 404; and Phyllis Wallace, 1982, ch. 2.) Several explanations have been suggested—such as blacks' greater marital instability, their extended-family households, black husbands' lower wages and less stable employment—but none has proved satisfactory. It seems that black wives' higher labor force participation is in large part a cultural difference, rooted in the historical experience of blacks in America, and not explainable by current conditions alone.

No one has yet attempted to measure and account for the differences in wives' labor supply among the other ethnic and nativity groups, as this paper will do. These differences are large, with the variation in annual *LFPRs* among ethnic and nativity groups being greater than the variation in annual hours worked for those in the labor force, as shown in Table 1. The ranking of groups in terms of annual hours worked by those in the labor force differs from the ranking in terms of *LFPRs*. This suggests that different parameters govern the participation and hours worked decisions, perhaps because the groups face different fixed costs of working. These two aspects of labor supply therefore need to be analyzed separately. In this paper I focus on the differences in labor force participation rates.

TABLE 1—LABOR SUPPLY OF MARRIED WOMEN  
AGES 18–64

	Annual LFPR	Average Annual Hours: $H > 0$
U.S. Born		
Asians	.711	1639
Blacks	.664	1536
White Non-Hispanics	.589	1383
Hispanics	.553	1346
Foreign Born		
Asians	.536	1524
White Non-Hispanics	.533	1450
Hispanics	.467	1459

Source: 1976 *Survey of Income and Education* micro data file.

The American-born groups all have higher *LFPRs* than the foreign born. The U.S.-born Asian wives have the highest rate, followed by blacks, then American-born white non-Hispanics; while foreign-born Hispanic wives have the lowest rate. Part of these intergroup differences in married women's labor supply is no doubt due to differences in the opportunity set. Another part may be due to cultural differences in the utility function.

This paper is a first step toward explaining the differences in wives' labor supply among ethnic groups and between the native born and foreign born. I will ask to what extent married women's labor force participation varies across ethnic groups due to differences in their average age, health, location, and income levels; to what extent such culturally conditioned factors as language, family size and age structure, and education account for differences; and to what extent there is a cultural difference among ethnic groups in the extent to which women with the *same* language, number of children, and education work outside the home. Such an accounting will identify the questions that need further research to explain the intergroup differences in wives' labor force participation.

### I. Data and Methods

To answer the above questions, I estimate a reduced-form, linear probability model of labor force participation for married women age 18–64 for each of seven ethnic and nativity groups. I use data from the 1976 *Survey*

of *Income and Education* (U.S. Bureau of the Census). My model of labor force participation assumes that a woman is in the labor force if her expected market wage offer exceeds her reservation wage. The expected wage offer is determined by human capital characteristics and the reservation wage is determined by the value of home time and the fixed costs of working in the market. These in turn depend on personal and family characteristics.

My reduced-form equation has a dummy dependent variable indicating whether the woman was in the labor force (employed or unemployed) at least one week in 1975. On the right-hand side are a set of dummy and continuous variables, the determinants of the market wage offer and the reservation wage. The continuous variables include the husband's annual earnings in 1975; the family's other annual income in 1975 (excluding the wife's and husband's earnings, and earnings-related transfers); the AFDC benefit available if the family had no income; the number of children under age 6, ages 6–11, and ages 12–17; the number of other adults ages 18–64 and over age 65 in the household (besides the husband and wife); and the wife's educational attainment. Dummy variables indicate the wife's race and ethnic group, her age (in ten-year intervals), her date of immigration to the United States (if foreign born), whether she lacks fluent English, whether she had a non-English mother tongue (if U.S. born), whether she has a health limitation, whether she lives in a metropolitan area, whether her husband is over 65, and whether he is self-employed.

Having estimated this model, I then separate the difference in predicted *LFPRs* between U.S.-born white non-Hispanics and each ethnic-nativity group into several components: one set due to differences in average characteristics, and another set due to differences in parameters of the labor supply function. The results of this decomposition obviously depend on the weights applied to the differences in characteristics and parameters. My solution to this index-number problem is to use the average of the two groups' sets of weights. I interpret the difference in parameters as reflecting systematic cultural differences in the utility function across

ethnic-nativity groups, for women with given personal and family characteristics. Because many of the intergroup differences in average characteristics are themselves influenced by cultural attitudes (such as language, family size, education of women), I show separately the difference in *LFPRs* attributable to each type of characteristic.

The linear probability model is a linear approximation to a nonlinear probit or logit model, which makes it convenient for separating an intergroup difference in *LFPRs* into components. The estimated coefficients are nearly identical to the partial derivatives of the probit or logit model evaluated at the variables' means. Using the reduced-form estimates for this decomposition raises a potential problem: if, due to discrimination or labor market segmentation, members of a group receive a lower market wage offer than their human capital characteristics warrant and therefore participate less in the labor force, we would find a difference in the estimated parameters and would attribute their lower *LFPRs* to culture rather than to discrimination. However, this is not in fact a serious concern because there is little evidence of wage discrimination *among women* by race or ethnicity (see my 1985 article). In any case, in the present study I find no evidence of *lower* labor force participation due to a difference in parameters.

## II. Results

Tables 2 and 3 show the components of the differences in *LFPRs* between U.S.-born white non-Hispanics and other groups. (The means and estimated parameters of the labor force participation function for each group may be obtained from the author upon request.) According to these estimates, if the groups had the same average characteristics (other than ethnicity, race, date of immigration, and mother tongue), native-born white and foreign-born white and Hispanic wives would have virtually the same *LFPRs*, and U.S.-born Hispanics would have a 2 percentage-point *higher* rate than U.S.-born whites. Gone would be all of the gap between U.S.-born and foreign-born whites, and 95 percent of the gap between U.S.-born whites and foreign-born Hispanics. More-

over, 75 percent of the gap between U.S.-born whites and foreign-born Asians would be closed, leaving only a 1.3 percentage-point difference in *LFPRs*.

On the other hand, the gaps between U.S.-born whites and U.S.-born Asians and blacks would be *widened* (substantially so for blacks), so that black and Asian American wives would both have *LFPRs* 12 to 13 percentage points above U.S.-born whites. Thus, differences in characteristics fully account for the lower *LFPRs* of Hispanic and foreign-born white and Asian wives, but completely fail to explain the higher *LFPRs* of U.S.-born Asians and blacks. Of course, cultural differences may be lurking behind some of the differences in characteristics, especially language, family size and age structure, and education. I next examine the effects of particular characteristics on wives' *LFPRs* and their contribution to the difference among ethnic and nativity groups.

As immigrant groups gradually assimilate to American society, cultural factors may result in labor supply differences between second generation women and those from the third and later generations in the United States. Having a non-English mother tongue (i.e., language used in one's childhood home) may therefore help explain labor supply differences among the U.S. born of different ethnic groups. I therefore include the effects of mother tongue among the differences in parameters that I attribute to "culture." However, this variable, which always has a positive coefficient, does not contribute to explaining the labor force participation gap for any group.

Lack of fluency in English is the most important difference between foreign-born Hispanics and Asians and U.S.-born whites. It explains a *LFPR* difference of .043 for foreign-born Asian wives, over 80 percent of their gap with U.S.-born whites. It explains a gap of .06 for foreign-born Hispanics, half of the total difference. For foreign-born whites, English explains a .01 difference, or only about 20 percent of the gap.

Differences in family size and age structure account for about a .05 gap in *LFPRs* between U.S.-born whites and Hispanics and a .03 gap for foreign-born Asians, whose

larger number of other adults partially offsets their larger number of children. This is more than the total difference between U.S.-born whites and U.S.-born Hispanics and a little over half of the difference for foreign-born Asians; but for foreign-born Hispanics, it is less than half of the *LFPR* gap. Blacks' larger families tend to reduce their labor force participation, so this cannot help explain their higher *LFPR*. The U.S.-born Asians have the same number of children as whites, but have more other adults and elderly at home. Both of these increase their *LFPR* (though the estimate is not significant), but this only explains 1 percentage point of the 12-point gap between them and U.S.-born whites. The foreign-born and U.S.-born whites are so similar in family size and structure that this cannot account for any of the *LFPR* gap between them.

Differences in education are among the biggest factors in the *LFPR* differences. Education explains a gap of nearly 6 percentage points between U.S.-born whites and U.S.-born Hispanics (more than 100 percent of the difference). It accounts for gaps of 5.4 points for foreign-born Hispanics, 2.4 points for foreign-born whites, and 1.2 points for foreign-born Asians. These are less than half the differences in *LFPRs* for these groups. Since U.S.-born Asian and white wives have the same education levels, this cannot account for any difference between them in labor supply. For blacks, the education difference, like the difference in number of children, works to lower labor force participation. Neither can help explain the black wives' high *LFPRs*.

The variables for immigrants' entry date and for ethnicity act as intercept-shifters, and their effects are attributed to cultural differences between groups. The entry date may also reflect an aspect of human capital: the acquisition of skills and information specific to the U.S. labor market. Insofar as I have wrongly attributed a human capital difference to a difference in parameters, my estimates of the difference due to culture are positively biased. If so, a more accurate measure would show the foreign born having even higher participation rates, if their characteristics were the same as U.S.-born whites.

My estimates provide strong evidence that immigrant women take just a few years to adjust to the United States before entering the labor force. In all groups, those who have been here at least four years are significantly more likely to be in the labor force than new arrivees. Labor force participation does not appear to change much with time in the United States after the first three years, aside from special "entry cohort" effects, such as the 1960-64 Cuban or the pre-1965 Asian immigrants.

My model also includes sets of dummy variables identifying ethnic origin insofar as possible. These dummy variables show any remaining difference in average *LFPRs* between ethnic groups, after all the measured characteristics have been taken into account. They therefore reflect what I interpret as a cultural difference in labor supply. For example, wives of German and British origin have the highest *LFPRs*, and Italians have the lowest among the identifiable groups of U.S.-born whites, given the same measured characteristics. Cuban wives have the highest and Puerto Ricans the lowest *LFPRs* among Hispanics of both nativity groups. Japanese American women have the highest *LFPR* among the U.S.-born Asian groups, but Filipino women have the highest rate among foreign-born Asians. Since 50 percent of the U.S.-born Asian wives are Japanese American, their high *LFPR* explains almost half of the Asian Americans' 12-point higher rate.

### III. Summary and Conclusions

I conclude, then, that the lower labor force participation of foreign-born white and U.S.-born and foreign-born Hispanic wives than U.S.-born whites is entirely due to differences in measured characteristics; no cultural difference in parameters appears to exist. A difference in parameters contributes a small amount to explaining the gap between U.S.-born white and foreign-born Asian wives; but it, too, is due mainly to the difference in characteristics—especially culturally influenced ones: language, family size and age structure, and education. Given the popular image of Hispanic culture, my finding that Hispanic wives who have the same schooling,

English, and family size as Anglo women participate even more in the labor force may come as surprise, but Vilma Ortiz and Rosemary Cooney (1984) also find traditional beliefs per se are unimportant for behavior. The influence of the Hispanic culture on married women's labor force participation works entirely through fertility, education, and language.

In contrast, for U.S.-born Asian and black wives, the entire difference from U.S.-born whites is due to direct cultural effects on the parameters of the labor force participation function, which account for a 12 to 13 point gap. The U.S.-born Asians (half of whom are of Japanese ancestry) have characteristics quite similar to U.S.-born whites. For blacks the cultural difference is larger than the actual difference in labor force participation; their characteristics lower their *LFPR*. Current personal and family circumstances cannot explain the high *LFPRs* for U.S.-born Asian and black married women; apparently we must turn to history to understand the cultural patterns that produce them.

# Peddlers Forever?: Culture, Competition, and Discrimination

By WILLIAM A. DARITY, JR. AND RHONDA M. WILLIAMS\*

Contemporary economic theory has all but completed the burial of the idea that market discrimination explains racial wage differentials or differences in general pecuniary accomplishments across ethnic groups under competitive conditions. We need only await the eulogy.

Interment began with the failure of the model premised on employers' taste for discrimination. The preferences of employers for members of one group over another could not sustain wage differentials under competition if the individuals from each group were equally able. Although the initial argument was made under the assumptions of neoclassical perfect competition, it was beaten back by the Austrian process view of competition (see Israel Kirzner, 1973). A latent reservoir of alert entrepreneurs presumably would seize the profit opportunities generated by the discriminatory wage gap, drive discriminating employers from the market, and erode the wage differentials.

Valiant efforts emerged subsequently to raise from the dead the idea that competition might eliminate market discrimination. These efforts involved the development of market discrimination models under the states of affairs characteristic of neoclassical imperfect competition or so-called "statistical" discrimination. Neither case precluded the possibility of ingenious entrepreneurship nor "the entrepreneurial capacity to smell profits" (Kirzner, p. 229). As a result, in neither case could the existence of wage or earnings differentials be maintained by employer decisions. In the first case, the inventive en-

trepreneur could circumvent or bring down the barrier that was the source of the imperfection. Similarly, in the second case the clever entrepreneur could devise new procedures for overcoming existing informational discrepancies that might exist about the abilities of the members of each of the ascriptively distinct groups (see Darity, 1982). The application of the Austrian process view of competition to the problem of racial and ethnic wage differences stripped market discrimination of its analytic significance.

However, the empirical persistence of such wage differentials in the U.S. economy is well established. The demise of the theory of market discrimination under competitive conditions has led to increasing use of the human capital explanation for differences in economic achievement across ascriptively distinct groups. After many years and scores of statistical studies that revealed that convergence in observable human capital characteristics—especially years of formal education—did not lead to the anticipated abolition of black-white wage gaps (see Williams, 1984), there is now a shift underway that identifies the source of the alleged human capital differences as unobservable cultural differences between ascriptively distinct groups. Cultural variation is accorded primacy in explaining ethnic and racial differences in economic achievement. In light of the death of the market discrimination explanation, the culturalological explanation is given added force by the observation that certain ethnic groups (Japanese and Jewish Americans, to name but two) have managed to succeed despite discrimination (see Barry Chiswick, 1983a, b).

The themes of culture and competition thus are the focus of this essay. We first provide substantive and historical critiques of the "new" cultural variant of the human capital theory. Second, we argue that the existence of ongoing market discrimination can be revived by employing an alternative

\*University of North Carolina, Chapel Hill, NC 27514, and University of Texas, Austin, TX 78712, respectively. Research support was provided by the Southern Center for Public Policy Studies at Clark College in Atlanta.

conception of competition rather than partaking in the wholesale denial of the importance of market discrimination. Specifically, classical and Marxist competition are proposed as alternatives to the neoclassical and Austrian views of competition. The former can be reconciled with the existence of market discrimination as a persistent source of differences in racial and ethnic group achievements.

### I. Culture as Human Capital: Logical Foundations?

Both Thomas Sowell (1981a, b; 1983; 1984) and Chiswick (1983a, b) have been in the vanguard of those proposing cultural explanations of racial and ethnic success or failure in the marketplace. Sowell describes culture as "ultimately ways of accomplishing things" (1983, p. 136) and argues that culturally produced attitudes and work habits often are the crucial determinants of group achievement. Chiswick conjectures that the higher rate of return to education enjoyed by second-generation Jewish immigrants to the United States: "may arise from cultural characteristics that enable Jews to acquire more units of human capital per dollar of investment...or it may be that there are cultural characteristics that enable Jews to be more productive in the labor market with the human capital embodied in them" (1983b, p. 334).

Moreover, Sowell in particular suggests that cultural differences are longstanding. In a telling discussion of the persistence of cultural inheritance, Sowell refers to the Jewish peddlers who trailed the Roman Empire's armies and their counterparts 2000 years later:

...[T]he reality of group patterns that transcend any given society cannot be denied. Jewish peddlers followed in the wake of the Roman legions and sold goods in the conquered territories. How surprising is it to find Jewish peddlers on the American frontier or on the sidewalks of New York 2000 years later—or in many other places in between? [1984, pp. 28–29]

Thus Sowell invokes the persistence of cultural traits and the continued possession of that culture by the direct descendents of the persons with those traits. But why do these traits persist, and why do they remain contained within a particular group? Sowell dismisses biological determinism in favor of pure cultural determinism with the cavalier remark that "no one needs to believe that Jews are genetically peddlers" (1984, p. 29). At the turn of the century, however, when intellectual conflict was greatest among proponents of culturally and biologically determinist views of human social evolution, there were those among the latter group who claimed the phenomenon of culture was "subordinate to nature" (see Derek Freeman, p. 21). The cultural determinists tended to argue that culture was self-organizing and self-reproducing. In what follows, we consider the logic and implications of cultural determinism.

From the pure cultural determinist perspective, culture is an attribute that can be changed, albeit with difficulty. Among economists, Richard Easterlin (1981) has advanced the view that (i) culture is malleable, and (ii) the whole world will become developed and culturally uniform—from the standpoint of the traits pertinent to economic advancement—as modern education simultaneously transmits those traits and signals their spread. As long as the predisposition toward certain cultural traits is not treated as innate or inherent—as given in nature—it can be transferred between members of various groups.

Furthermore, if some groups possess cultural attributes that enhance their performance in an environment where market exchange is a major aspect of social life, then we would expect incentives to emerge for members of the culturally advantaged group to transfer those attributes to less favorably endowed groups. The "new" cultural variant of the human capital theory presumes a persistence of market-valued cultural differences that is at odds with the conception of competition that undermined the theoretical persistence of market discrimination.

If ethnic differences in economic achievement are long-lasting because cultural dif-

ferences are long-lasting, then logically there must be a failure of the market mechanism to complete the transfer of the appropriate cultural norms from the high achievers to the low achievers. Hence, the variation in ethnic or racial economic accomplishment has to be explained by a failure of competition, which must mean a failure of entrepreneurs to recognize the source of variations and conduct the transfer. But why should the alert and inventive entrepreneurs fail here when they are assumed to have succeeded so admirably in destroying market discrimination? The Austrian competitive process that ostensibly can destroy a host of impediments to the free operation of the market is somehow immobilized when confronted with cultural differentiation. It was precisely because the competitive process was seen as so strongly operative that the cultural argument has gained such sway in some quarters of the profession, in spite of the logical inconsistency. Either Austrian entrepreneurs can undercut both market discrimination and cultural differentiation, or they can do neither.

One would expect cultural differences to persist if the more successful ethnic group can withhold its "trade secrets" from the marketplace. This means the economic theorist must explain how the successful group enforces sanctions against cultural transfers in the presence of opposing incentives the market might offer—that is, how do they prevent cartel cheating on an indefinite basis?

To recapitulate: if one accepts the position that cultural differences are significant determinants of ethnic and racial economic inequality, then one must explain why cultural differences salient for success are persistent. This persistence is impossible to maintain if one believes the market system is imbued with an Austrian process of competition. Sowell (1981b), for one, seems to have in mind exactly such a view of competition.

## II. Culture as Human Capital: Historical Foundation?

After comparing the socioeconomic achievements of various Asian-American ethnic groups (the Chinese, the Japanese, and the Filipinos), Chiswick notes that: "The

findings for the Chinese and Japanese suggest also that it is incorrect to assume that racial minority status in the United States and racial discrimination *per se* result in lower observed levels of earnings, schooling, employment, and rates of return to schooling" (1983a, p. 212). Chiswick correctly calls our attention to the substance of discrimination and leads us to inquire whether all racially identifiable nonwhite groups experienced similar patterns of "discrimination *per se*."

Considering first the case of American Jews, it has by now been well documented that Jewish immigrants from Eastern Europe made major income and occupational gains well before their children attended, en masse, those public institutions of higher education which provided avenues for the upward mobility of subsequent generations (see Selma Berrol, 1976; Sowell, 1981a, pp. 90–91; Stephen Steinberg, 1981, chs. 3, 5). The rapid socioeconomic progress of the immigrants was, in turn, facilitated by the historical juxtaposition of their unique constellation of skills and a growing, dynamic economy very much in need of those talents. Excluded from land ownership in Eastern Europe, urban Jews developed the petit bourgeois skills (including a high degree of literacy) which served them so well once entrenched in the urban centers of turn-of-the-century industrial American capitalism. Moreover, the entrepreneurial beginnings of Jewish peddlers, merchants, and clothiers provided the material base for the educational and occupational mobility of the next generation of college graduates.

West Indian immigrants provide another example of the importance of evaluating immigrant economic development in terms of class background and the opportunity structure of the receiving nation. West Indian incomes and occupational attainments are often cited as evidence that discrimination *per se* cannot explain the economic status of native black Americans, since so many Caribbean blacks have fared so well. In one of his many discussions of the gap between West Indian and native black American incomes, Sowell suggests the discrepancy is one more piece of evidence that "...cultural traits reaching far back in history have continuing

contemporary impact..." (1981c, p. 50). How, then, do we explain the less than sterling achievement of this same culture when functioning elsewhere—say at home in the (poverty stricken) West Indies or in Britain? Sowell acknowledges that this same culture has proven less remunerative in the West Indies (1983, p. 107), but is silent as to the reason.

Cultural explanations fail in a historical context because they consistently exclude considerations of social class. Nancy Foner (1978, pp. 229–31) reports that the Jamaicans who moved to London were of a lower socioeconomic background than their highly educated and skilled counterparts in New York City, the difference a function of respective British and U.S. immigration policies. The central point remains unaltered. West Indians in Britain and those still at home in the Caribbean share the same national culture with West Indians in the United States, but they did not share the same prior class position.

### III. Classical and Marxist Competition: Discrimination Revived

The logical problems with the cultural explanation for racial and ethnic inequality are compounded by its inadequacies in explaining the experiences of specific ethnic and racial groups. But the only reason that economic theorists have plunged into the wasteland of cultural primacy is because of the irreconcilability of market discrimination and competitive conditions. In this final section, we suggest that there are at least two conceptions of competition that can bring market discrimination back from the grave—classical and Marxist.

Classical competition (see Piero Sraffa, 1960) is rooted in the notion that there exists a tendency toward the equalization of rates of profit. Neither barriers, rigidities, nor numbers of producers in a given product market come into play so long as finance is mobile; capital must "earn" the same return in all sectors.

Suppose firms vary in productivity—with high wages in the high productivity sector, low wages in the low productivity sector and with whites in the former sector and blacks

confined to the latter. Wage differentials persist between blacks and whites of equal ability because productivity is determined by the sectoral techniques of production.

Neoclassical competition presumes labor mobility will equalize wages across sectors. If rates of return equalize, the ratio of final product prices is determined by the labor-output ratios in each sector. Austrian competition presumes entrepreneurs will move low-wage workers into the high-wage sector, initially benefiting by paying them the lower wage, but eventually eroding the wage gap. So long as rates of profits tend to equalize across sectors, these adjustments are not concerns for classical competition. Classical competition reconciles market discrimination and competition by definitionally permitting impediments or rigidities that cannot exist or persist under neoclassical or Austrian competition. Classical and neoclassical competition thus share a common inclination to define competition as a specific "state of affairs" and proceed to analyze its properties. In contrast, both Austrians and Marxists conceive of competition as a process, but differ as to the expected outcomes of the process.

Marxian competition subsumes the Classical notion, but introduces an evolutionary view (Karl Marx, 1981; John Weeks, 1981, ch. 6). Competition between capitals postulates the separation of labor from the means of production and is the means whereby the underlying laws of accumulation achieve expression. As a social relation, capital represents the integration of production and exchange in an expanding circuit, and competition between capitals arises in this integration (Weeks, p. 160). Since the market for labor power is the necessary condition for competition between capitals, the existence of capitalism implies competition (see Marx, Part 2). And, as Weeks notes, "Capitalism involves the movement of capital; competition is that movement" (p. 164).

The evolutionary nature of Marxist competition simply means that competition gives rise to monopolies, but monopoly is not the antithesis of competition. Centralization (the redistribution of existing capital) intensifies and advances competition, which is manifested in the flow of capital between branches of industry. Marx's capitalist winners con-

solidate and concentrate; they can exclude the losers and consolidate their positions for long stretches of time. Austrian competition's winning entrepreneur cannot, in contrast, *permanently* maintain barriers to preserve his position (Kirzner, pp. 131, 205). According to the Austrian view, barriers will eventually be torn down by newer contestants.

We extend Marxist competition to labor powers. Workers also can concentrate and consolidate, particularly by ethnicity or race. Via the control of training, evaluation, information, and the definition of jobs, winners in early rounds of labor market competition can insulate themselves from the most recent recruits to the wage labor force. Here lies the basis for Edna Bonacich's (1976) "split labor market," where capitalists face a labor market differentiated in terms of bargaining power and therefore price, for Oliver Cox's (1970) analysis of the racial and ethnic division of the labor force in a class-based society, and for Stanley Lieberman's queuing labor market model wherein "dominance will tend to perpetuate further dominance" (1980, p. 296).

What place remains for culture? Under classical competition with market discrimination, culture need not play any role. Austrian competition conceives of a world with entrepreneurs who heroically can render asunder all barriers. In such a world, the persistence of both market discrimination and premarket cultural differences is untenable. Marxist competition conceives of a world that tends toward monopoly. Specific ethnic and racial groups could gain control and dominance of particular occupational categories. They act to preserve their "winnings" in a fashion that is not "normal" under Austrian competition. Culture is the magnet that provides the basis for concentration of labor powers.

Extension of the Marxist conception of competition to labor powers is a relatively new theoretical endeavor, but nonetheless one with both precedent and explanatory power. Pursuit of this line of inquiry necessitates investigation of the concrete economic and historical conditions confronted by specific ethnic and racial groups. Without such an investigation, cultural analysis becomes the cornerstone for constructing what Steinberg

(p. 77-81) describes as the "New Darwinism," in which culture is passed between generations and guarantees that good things happen to the culturally efficient, and social pathology is the tragic misfortune of the cultural misfit.

## Women Production Workers: Low Pay and Hazardous Work

By JANIS BARRY\*

The sex segregation of the labor market is reflected in the underrepresentation of women in production jobs. In the last decade, although women have slowly entered male-intensive and better-paid production jobs, they have found greater wage inequities and more hazardous working conditions than in their traditional nonproduction jobs. Women generally have been concentrated in health-hazardous industries (such as apparel, chemical, leather, and electrical equipment), and there is significant evidence of institutional and historical forces that operate to keep them in the lower-paid production jobs within these and other industries. This has encouraged research showing that jobs women hold are differentially evaluated; this paper provides evidence of unequal rewards paid to women in hazardous jobs. Average differences in this and other job and personal characteristics between men and women are used to explain the earnings gap. A segmented labor market model is also used to derive earnings-gap explanations and to explore the importance of segment location in determining job rewards for similarly qualified workers.

### I. Conceptual Framework

During the last decade, various studies have considered the market's performance in equalizing the net advantages between jobs (Charles Brown, 1980). Neoclassical economists assert in this literature that workers are

induced into accepting jobs with disagreeable or hazardous conditions by the compensating wage differentials that employers must offer to meet competition. But due to market inadequacies that include imperfect hazard information, constrained job mobility, and underestimation of injury and disease costs, the evidence on compensating wage differentials remains inconclusive.

Segmentation theorists credit wage differentials and disparities in working conditions to the existence of not one but many labor markets, to which some workers are confined—not allocated. In effect, the neo-classical assumption that all workers are able to enforce “implicit contracts” of tradeoffs between working conditions and wages cannot hold; instead, the balance of power established between workers and their employers will resolve the question of whether working conditions degenerate, improve, or are compensated for. And bargaining power is necessarily influenced by particular historical and institutional factors. Thus, in an economy where good jobs are scarce, segmentation theorists find that otherwise qualified workers are excluded from primary-sector jobs, jobs where internal labor markets operate to promote equity and due process in the administration of work rules, high wages and uniform working conditions (David Gordon et al., 1982). This exclusion is particularly felt by women and minorities, who face strong institutional restrictions on their job choice.

While theorists disagree as to the source of labor market segmentation, many agree that primary and secondary markets are distinguished by firm characteristics and the job systems they employ. Segmentation analysis separates the primary from the secondary market on the basis of both industrial and occupational characteristics, where the meth-

<sup>†</sup>*Discussants:* Shulamit Kahn, University of California-Irvine; Luvonia J. Casperson, Louisiana State University-Shreveport.

\*Department of Social Sciences, Fordham University at Lincoln Center, New York, NY 10023.

od of categorization relies on the characteristics of jobs and not those of workers.<sup>1</sup> Production jobs in the independent primary segment are thought to provide incentives to stability in the form of high pay with some job security and rewards to general skills (this includes professional, technical, and craft jobs). Jobs in the subordinate primary segment (including blue-collar jobs in core industries) are thought to provide decent wages and advancement possibilities through internal labor market operations. Secondary jobs (including many operative and laborer jobs in peripheral industries) are thought to provide few incentives to stability because of insecure employment, low wages, few promotional possibilities, and no shelter from competitive market forces (Gordon et al.).

In previous research (1983), I found that production workers in high-risk industries and occupations receive, on average, an equalizing differential. Yet using a segmentation analysis, I found that not all personal and job characteristics are equally rewarded across segments and that compensating differentials for hazardous work are segment-specific. My earlier study also found evidence that worker-perceived hazards are most prevalent in the secondary sector, where 50 percent of all women workers are located. In fact, among all workers, women in this segment most often cited these problem-creating hazardous exposures. Thus, the question arises: do women in hazardous jobs receive compensatory wages? Further, what is the relative importance of labor-segment location in determining compensatory pay for hazardous work?

## II. Compensatory Wages for Women and Men

To specify better how the differential evaluation of jobs women hold encourages earnings inequities, I used a regression analysis to test the compensatory wage theory

using a random sample of 528 production workers. Data sources used for this investigation include the 1977 *Quality of Employment Survey (QES)* and the *Dictionary of Occupational Titles (DOT)*, from which I constructed an occupation-level hazard measure (*HAZARD*). This measure represents the mean score on six environmental conditions (cold, heat, wet, hazards, atmospheric conditions, noise) associated with the worker's occupation, as given by the *DOT*. I calculated the annual income earned on the job by each full-time worker and used the natural logarithm of this variable as the dependent variable in the earnings equation, where independent variables were worker and job characteristics.

The first regression analysis tested the alternative hypothesis that, *ceteris paribus*, there exists a positive wage differential between those workers in hazardous jobs and the wages of all other workers. The evidence shows that workers in jobs with higher mean *HAZARD* scores do indeed receive a compensatory differential. This same test was made for both men and women workers.

Table 1 shows that for men, the *HAZARD* coefficient is significant and positive. Yet the women's sample shows that women production workers earn less the more hazardous the job they hold! Comparisons between the variable means for the two samples show that the mean score on the *HAZARD* measure for women is 43 percent that of men's and, insofar as women are less likely to work in more hazardous jobs, an insignificant coefficient on this measure would seem plausible. But the unexpected finding of negative earnings premiums in hazardous jobs discredits the alternative hypothesis. In contrast to men, women are not rewarded for choosing hazardous jobs. Assuming that the women in the sample are homogeneous apart from their aversion to risk, this finding may show that women are unable to successfully exploit the same bargaining opportunities presented to men by the work environment. In Table 1, the union membership variable is significant for men but not for women, perhaps reflecting a weaker union effect on earnings within those industries where women hold more hazardous jobs.

<sup>1</sup>To avoid truncation bias, segmentation models must not base their classification of workers into segments on worker attributes such as gender, race or earnings. See Robert Buchele (1984, p. 216) for a discussion of cause vs. effects.

TABLE 1—MEANS AND REGRESSION COEFFICIENTS FOR WOMEN AND MEN<sup>a</sup>

Independent Variables <sup>b</sup>	Women		Men	
<i>HAZARD</i> <sup>c</sup>	.50	-.2104 <sup>c</sup> (.0823)	1.16	.0805 <sup>d</sup> (.0271)
<i>FRINGE BENEFITS</i>	3.56	.1093 <sup>d</sup> (.0262)	4.35	.0507 <sup>d</sup> (.0127)
<i>HAS JOB SECURITY</i>	.62	.2164 <sup>c</sup> (.0924)	.72	.0321 (.0526)
<i>UNION MEMBER</i>	.41	.1911 (.1119)	.47	.2522 <sup>d</sup> (.0476)
<i>OVERTIME</i> <sup>f</sup>	.15	.1565 (.1179)	.33	.2122 <sup>d</sup> (.0502)
<i>JOB REQUIRES SKILL</i>	.38	.0011 (.0918)	.68	.1851 <sup>d</sup> (.0517)
<i>SUPERVISOR</i>	.06	-.0359 (1.689)	.29	.1241 <sup>c</sup> (.0535)
<i>N</i> (number of observations)		72		333
<i>R</i> <sup>2</sup>		.630		.309
<i>ln</i> (annual earnings)		8.763		9.396

<sup>a</sup>Dependent variable = *ln* (1977 annual earnings). The random sample of 528 production workers is taken from the 1977 *QES*, representing workers in #401-785 and #821-824 in 1970 Census codes. Individuals with missing observations on variables entering the earnings equations are not included.

<sup>b</sup>Other independent variables used in the earnings equation are age; education; minority member; job is physically or mentally demanding; job has bad physical working conditions; repetitive work; and job tenure. These measures are described more fully in my earlier study.

<sup>c</sup>Significant at .05 level.

<sup>d</sup>Significant at .01 level.

<sup>e</sup>Mean score for six conditions.

<sup>f</sup>Minimum 10 hours per week.

In the *QES*, women production workers earned on average \$6,398 yearly and men, \$12,043. Using a decomposition procedure, we can investigate how much of the male-female earnings differential can be attributed to measured average differences in job and personal characteristics between genders. Estimations are obtained by subtracting the female mean for each independent variable from the male mean, multiplying the difference by the male regression coefficient, and expressing this project as a fraction of the differences in *ln* earnings between women and men. Of particular interest, we find that average differences between men and women on the *HAZARD* measure accounted for 8 percent of the earnings gap. Yet the standardized regression coefficients show that

the negative impact of this measure on women's earnings is almost twice the positive impact observed on men's, putting the reliability of this gap explanation in question. In general, the evidence reflects the structural constraints placed on women's pay opportunities, with job and personal characteristics cumulatively explaining only 35.2 percent of the earnings gap.

### III. Compensatory Wages within Segments

Using the same data as was used for the regression analysis for men and women, the production-worker sample was assigned to either the primary labor market (further disaggregated into the independent primary professional and technical segment, the independent primary craft segment, and the subordinate primary segment), or the secondary labor market.<sup>2</sup> A breakdown of mean *HAZARD* scores by segment shows them to be highest in the independent-craft and subordinate primary segments for both men and women. It is these workers in particular who should be earning compensating pay differentials. But separate earnings regressions by segment show that for men, secondary workers are the only group to receive a compensating differential, despite their comparatively lower *HAZARD* scores. This reflects the greater wage dispersion among men in the secondary sector, where external market forces determine earnings. Due to an insignificant sample size, separate earnings regressions for women could only be made for secondary workers; the results show a negative return on *HAZARD*, although the insignificance of the coefficient is assumed to reflect sample-size limitations. However, large earnings differences between men and women in the primary sector allows us to conjecture that women here also may realize negative returns for hazardous work because of their location in nonunionized entry-level jobs and their inability to gain the same

<sup>2</sup>The model used here (see Gordon et. al.) relies on an industry-by-occupation analysis of job characteristics, distinguishing between core and peripheral industries and those jobs which do encourage skill application.

internal labor market benefits enjoyed by men.

By comparing female-male earnings ratios within segments, I found that women in traditionally male-intensive jobs in the primary sector generally find greater pay discrimination. Women realize their greatest equity (64 percent of male earnings) in professional and technical jobs in the independent primary segment, although they represent only a scant 4 percent of all workers. Interestingly enough, women do almost as well (60 percent of male earnings) in the more female-intensive secondary sector. Yet women in craft and semiskilled jobs located in the independent primary craft and subordinate primary segments respectively earn only 43 percent and 53 percent of men's earnings.

An estimate of the cost of women's differential allocation to labor segments indicates that *ceteris paribus*, if men and women were distributed proportionally across labor segments, men would decrease their earnings by 4.9 percent and women would decrease their earnings by 7.6 percent.<sup>3</sup> An important implication of this finding is that to merely move women out of the secondary segment where they are concentrated and into the more male-intensive jobs in the primary sector would not increase their earnings unless their pay reflected an unbiased assessment of the true, relative worth of these jobs (see Robert Buchele).

Lastly, segment breakdowns of earnings differentials cumulatively explain much less of the overall gender gap because of the greater homogeneity of job and personal characteristics within segments.<sup>4</sup> But more of

the gap is explained in the secondary sector where the structure of competition largely determines the worth of women's jobs.

#### IV. Conclusions

Although compensatory wage theory stipulates that workers who assume greater risk on the job will receive additional earnings (other things being equal), my findings show that the gender composition of jobs influences the pay rates in cases of hazardous work. In general, men receive compensatory wages and women do not; specifically, women earn less the more hazardous their occupation. Women's concentration in the secondary market, where workers' bargaining power is weak, does not satisfactorily explain this, since the evidence shows that women in the more hazardous primary-sector jobs, where bargaining power is greater, generally have lower female-male earnings ratios than are found in the secondary sector. This reflects the unequal bargaining power between women and men regardless of labor-segment location. In contrast to men, the structural location of women's jobs is not as important in determining general pay rates, or (by assumption) particular compensatory pay differentials for hazardous work.

<sup>3</sup>An adjusted earnings level (i.e., the antilog of the weighted average of the segment-specific ln earnings, where the weights are number of workers expected under the condition of no differential assignment to segments on the basis of gender) is compared to actual antilogged mean earnings for each gender.

<sup>4</sup>Weighting the three segment-specific gap explanations by the percentage of workers in each segment shows 22 percent of the total gap is explained for 92 percent of the sample. Earnings-gap estimates for primary professional and technical workers could not be made, but it is unlikely that this would change the total gap sum.

# Executive Compensation: Female Executives and Networking

By ROBIN L. BARTLETT AND TIMOTHY I. MILLER\*

The phrase "it's who you know, not what you know, that counts" is often heard in conversations about people who get ahead. In economic terms, this phrase translates into "it's your connections, not your human capital investments, that count." This study attempts to determine the influence of networking in addition to human capital investments by examining a sample of top female executives in the United States. We conclude that networking is as important as performance variables in helping women climb the corporate ladder.

## I. Executive Compensation: The Current Debate

To date, the primary focus of the executive compensation literature is the relative importance of firm size, as measured by sales and assets; and firm profitability, as measured by net corporate income or the rate of return on assets. The debate parallels the controversy over what is the primary objective of the modern corporation. Advocates of the neo-classical perspective believe that firms primarily maximize profits, and that more profitable firms have more productive executives, who thus earn more than executives heading up less profitable firms. Similarly, advocates of the managerial perspective argue that firms try to maximize sales given a reasonable profit margin. Thus executive compensation is directly proportional to firm sales. Although the debate as outlined by David Ciscel and Thomas Carroll (1980) continues, evidence is not compelling for

either perspective and there exists evidence that firm profits and sales are both important proxies for firm size. Although all of these studies have examined male executives, firm size and female executive compensation should be positively related.

Timothy Hogan and Lee McPheters (1980) go beyond looking at performance variables as the sole determinants of compensation, and add experience, education, and background characteristics as predictors of an executive's future performance. Typically, human capital variables such as these are not included in executive compensation models because sales and profitability variables are thought to capture an executive's contribution. As Hogan and McPheters demonstrate, however, in a world of imperfect information, personal characteristics such as experience, education, and background become important indicators of future productivity as suggested by the screening hypothesis or favorable training costs as implied by the job-competition hypothesis. A study by Naresh Agarwal (1981) compares the relative importance of human capital variables and organizational factors such as the layers of management and the firm's ability to pay. Agarwal concludes that human capital factors may be important for initial entrance, but organizational factors dominate personal characteristics thereafter.

Additional reasons for including human capital variables are: 1) ascribing a firm's performance totally to the performance of the chief executive officer is problematic; and 2) none of the women in our sample is the chief executive officer of a Fortune 500 firm. Thus, using the human capital theory (Gary Becker, 1964), an individual's compensation is directly related to her productivity; that is, in a competitive setting, an individual's wage is equal to the marginal net revenue product associated with her employment. Moreover, an individual's remuneration depends upon other factors in addition to her initial pro-

\*Professor of Economics and Associate Professor of Economics, Denison University, Granville, OH 43023. We thank Jacqueline Davis and Korn/Ferry International for making their sample of executive women available, and the Wellesley College Faculty Awards Committee for providing the funds necessary to secure it. We also thank Daniel Fletcher, Judy Thompson, and Sara Jean Wilhelm for editorial comments.

ductive capacities. Compensation grows over time as an individual accumulates human capital through additional formal education or informal on-the-job training. An executive with more experience, more and/or better education, and more general and specific training, *ceteris paribus*, should perform better on the job and earn a higher salary.

## II. The Female Executive

A great deal of attention is being focused on the new managerial women. The reason for such attention is that women are moving very rapidly into the managerial ranks. In 1961, 5.1 percent of the female labor force was in the managerial and administrative occupation. By 1981, the percent of the female labor force in that occupation had grown to 7.4 percent. The percent of the male labor force hovered around 13.5 percent over the same time period. The influx of women into the managerial ranks increased gender concentration (the percent of an occupation female) from 15 percent in 1961 to 27 percent in 1981 (U.S. Department of Labor, 1983). But, the income statistics do not indicate that managerial women are getting ahead. Female managers earned 58 percent of what male managers earned in the early 1960's, and twenty years later the ratio remains virtually unchanged (U.S. Department of Commerce, 1963; 1983). Firm profitability and size may account for this difference, human capital variables may account for this difference, female managers may be differentially motivated than their male counterparts, or female managers may have relatively limited access to labor market information. However, Linda Brown (1979) concludes in her survey article that there is no evidence of consistent motivational differences between male and female managers. Successful managers tended to be ambitious, willing to take risks, and the oldest child of a professional father. In a recent case study of two major retail firms, one with 19 percent and the other with only 6 percent of its managers female, Anne Harlan and Carol Weiss (1981) examined the unique background characteristics of these women and, the organizational gender biases of their

firms. While the managerial women in this study did not exhibit any motivational differentials as compared to their male counterparts, they did believe that being a woman was the biggest hindrance to their career. Both men and women in this study felt that women were given different training, development opportunities, promotional criteria, and supervision than men were. The interaction of individual characteristics and organizational gender biases resulted in limited advancement opportunities for women. If motivational and background characteristics do not explain the persistent wage gap, then information differentials need to be explored.

## III. Networks in a World of Imperfect Information

Without perfect information in the labor markets; that is, without buyers and sellers of executive talent having complete information, both groups need to engage in search activity. Albert Rees (1966) discusses the role of formal and informal information networks in labor markets. Since it is difficult for an executive to be knowledgeable about all the job possibilities in the market, she lists her name with an executive recruiting firm, and when a job possibility arises, pursues it. "Head-hunting" firms are an example of a formal channel of information. Friends and family are an informal source of labor market information. Although not as formal as an executive recruiting firm, nor as informal as family, clubs are a valuable source of labor market information. Social or service clubs tend to draw their members from similar socioeconomic backgrounds. Belonging to a large network of similarly situated professionals offers a greater opportunity for hearing about jobs (the extensive margin of job search) and a greater opportunity for finding out inside information about a job offer (the intensive margin of job search). Mary Corcoran, Linda Datcher, and Greg Duncan (1980) found that over 40 percent of all managerial jobs are discovered by word of mouth. Information is efficiently pooled and cheaply distributed through club affiliations. An executive who belongs to clubs would be expected to have better infor-

mation at both the extensive and intensive margins of job search. As George Stigler notes: "The information a man possesses on the labor market is capital: it was produced at the cost of search and it yields a higher wage rate than on average would be received in its absence" (1962, p. 103). In our study on the determinants of executive compensation with James Grant (1984), we found that male executives who belonged to clubs earned more than nonaffiliated executives. Female executives who belong to clubs should also earn more than female executives who do not.

#### IV. The Model

The model as developed (limited by the available data), is as follows:

$$(1) \quad Y = b_0 + b_1S + \sum (b_iH) + \sum (b_iB) \\ + \sum (b_iO) + \sum (b_iN) + U.$$

Equation (1) says that an executive's compensation  $Y$ , which equals salary plus bonuses, depends upon the size of her corporate employer  $S$ , her human capital investments  $H$ , her unique background characteristics  $B$ , her (perceived) organizational environment  $O$ , and her access to information networks  $N$ . The  $b_i$ s are the coefficients to be estimated and  $U$  is the disturbance term. The actual variables used in each category are listed in Table 1. Differences in these variables will lead to differences in individual compensation.

#### V. The Sample

In 1982, a questionnaire was designed by UCLA Graduate School of Management and Korn/Ferry International, an executive recruiting firm, to obtain a profile of the successful female executive. The questionnaire was sent to over 600 female executives from Fortune's top 1000 firms, and more than 50 percent were returned. Our sample consists of the 132 female executives who responded to those questions that were essential to our study. Some of the more interesting char-

acteristics of these women are: their average cash compensation is \$86,881; their average age is 41.9 years; overall, 26.5 percent graduated from an "Ivy League" college, 43.1 percent held some leadership position in college, and 13.8 percent participated in sports while in college. On average, these women worked 52.5 hours per week and 26.2 percent took a leave of absence during their career. Less than half, 48.2 percent, are currently married; 53.4 percent had fathers who were professionals; and 56.0 percent were the oldest child. When asked to rate their level of ambition on a scale of 1 to 5 (1 being least), the average value given was 4.207; 65.2 percent viewed themselves as "risk takers," and 47.0 percent are Republicans. Of particular interest to this study, 56.3 percent are members of private clubs and 20.9 percent serve on corporate boards. In terms of progress up the corporate ladder, 41.6 percent believe that "it's who you know, not what you know" that matters.

#### VI. The Regression Results

The model was estimated using both the linear and semilog specifications. In estimating our model, several persistent cases of multicollinearity occurred. Age, age-squared, and job tenure were gathered as measures of human capital, but because these women executives were all very similar, it was not possible to include more than one of these variables in the model. Age was chosen over age-squared, since the sample consisted of relatively young executives who were probably not at the peak of their careers. Age and job tenure were then included separately. The variable job tenure had a  $t$ -score less than .06, while age had a  $t$ -score greater than one. Since both could not be used, age was chosen. A similar problem arose in attempting to use "college degree," "Ivy League" college graduate, "Masters of Business Administration," and "held a college leadership position" as separate variables. The variables "held a college leadership position" and "Ivy League" college graduate were selected since the former measured an important antecedent background characteristic and the latter

TABLE 1—DETERMINANTS OF FEMALE EXECUTIVE COMPENSATION

measured educational credentials. Finally, the variables "took a leave of absence" and "number of children" were also considered as measures of unique background characteristics. These variables were statistically insignificant (*t*-scores were -.068 and .069,

respectively), and their presence in the model added substantially to the multicollinearity problem. The results are presented in Table 1.

Because cross-sectional data were used, heteroscedasticity was suspected as in previous studies. Both a Glejser test and a Goldfeld-Quandt test as outlined in John Johnson (1984, pp. 300-02) were performed. No evidence of heteroscedasticity was detected at the 10 percent level with either test.

## VII. Interpretation of Results

These results are a mixture of the anticipated and unexpected. Executive compensation is positively influenced by both the size of the corporation and the amount of effort put forth by the individual (as measured by the number of hours she works per week). The quality and/or quantity of one's formal education (as measured by "Ivy League") seems to have a positive effect upon compensation although experience (as measured by age) was not significant.

Contrary to our expectations, marriage was not an inhibiting factor for female corporate success. Two of the more disappointing results were the statistical insignificance of being an only child and having a professional father. If one considers that 56 percent of these executive women were oldest children and that over 53 percent had professional fathers, it seems improbable that these traits do not matter. Perhaps these factors would better serve to differentiate between women who become executives and those who do not. Neither being married nor being a non-Republican had the anticipated negative impact. Having been active in college sports had a positive impact on compensation, suggesting that this variable may be an indicator of the young woman's willingness to take risks and/or her learning to be a "team player."

These results strongly support Harlan and Weiss in their contention that organizational gender biases play a major role in limiting the advancement and compensation of female executives. Working in an environment in which discrimination is readily perceived has

a very strong negative impact upon a woman's compensation, no matter what her attributes or efforts. While it was noted earlier that women are entering management in increasing numbers, these results provide evidence that their progress up the corporate ladder is being impeded by other barriers.

The major premise of this paper is that "who you know" may be just as important as "what you know." This contention seems to be strongly supported by the results. Working environments in which knowing the right person is important for career advancement has a strong negative impact upon a female executive's compensation. In contrast to this, women who "plugged in" to networks, as measured either by memberships in private clubs or on corporate boards, profited substantially by these additional contacts and information. Thus, managerial women need more than larger corporations and greater human capital investments to be successful. In order to make the most of their opportunities and human capital investments, women need to be plugged in to networks that provide requisite labor market information.

# Longitudinal Changes in Salary at a Large Public University: What Response to Equal Pay Legislation?

By SHARON BERNSTEIN MEGDAL AND MICHAEL R. RANSOM\*

Legislation in the early 1970's greatly strengthened the legal status of women faculty at colleges and universities. The Equal Employment Opportunity Act of 1972 extended Title VII of the Civil Rights Act protection against sex discrimination in employment to academic personnel. In the same year, the Equal Pay Act of 1963 was expanded to cover university and college faculty, and orders from the Executive Branch required affirmative action plans of all federal contractors. The purpose of this paper is to determine the extent to which the salary structure at a large public university has changed since 1972. In particular, we use longitudinal data to examine how the University of Arizona responded to this legal environment with regard to employment and pay of female faculty members.

Many have gauged sex differentials in faculty compensation and offered reasons for their existence. The general empirical findings of these studies can be summarized as follows. After controlling for numerous factors, women tend to earn lower salaries than do men, and the difference is usually statistically significant. The differential tends to widen with length of service, while controlling for rank lowers its size, although rank assignment itself may reflect sexual discrimination in hiring and promotion (see Emily Hoffman, 1976; Burton Malkiel and Judith Malkiel, 1973). With few exceptions, most have used cross-sectional data for a single year. Changes in compensation practices in response to equal pay legislation have not been assessed. From a longitudinal point of view, the "wage gap" between com-

parable male and female faculty members at a given time can be thought of as arising from two different sources: differences in pay at the time of hire; and differences in rates of growth in salaries. If there is an institutional response to the changing legal environment, it must appear as a change in either or both of these factors. In what follows, we describe our data set and summarize our findings. As is suggested by our title, we find that significant unexplained salary differentials have persisted.

## I. Data

Our data set contains information on salaries and personal and employment characteristics of about 1900 individuals who were employed by the University of Arizona during 1972, 1977, and/or 1982. We restrict our analysis to career-type teaching faculty at the main campus of the university; administrators, professional and research faculty, and medical school faculty are excluded from the data set. We were able to identify salary, rank, tenure status, and departmental and collegial affiliation from the annual budgets of the university. From other published university records, we determined the date and type of highest degree and the date of hire. Sex was determined by name. In the case of unusual or ambiguous names, the sex was verified through personal communication. Some individuals are not included in our sample because of incomplete information.

From the raw data, we construct for each year the following variables: *SEX*, *PHD*, *SERV*, and *EXPR*. The variable *PHD* is a dummy equal to one if the individual has a doctoral degree, such as a Ph.D. or Ed.D. The variable *SERV* is defined as the years of service at the University, and *EXPR* is defined as the number of years since the individual received his or her highest degree.

\*Department of Economics, University of Arizona, Tucson, AZ 85721. We thank Cordelia Reimers and Michael Rieber for helpful comments.

Female	27374	10.19	.86	9.6	13.2

*SEX* is a dummy variable equal to 1 for females; *SAL* is the individual's salary, adjusted to a 10-month academic year, and *LNSAL* is the natural logarithm of salary.

Table 1 presents summary statistics for the basic variables of our analysis for the full university and for the Liberal Arts College. We chose to focus on a single college within the university because colleges have a lot of autonomy in employment decisions. The Liberal Arts College was selected for its relatively large number of women. Corresponding sample sizes *N* (total) and *NF* (females) are reported in Table 2. There are rather striking differences between males and females. Male salaries average 22 to 28 percent more than female salaries, with the ratio increasing over time. Over the same period, average *EXPR* and *SERV* of females have declined substantially relative to male averages. This is due primarily to the much higher rate of turnover among females. For exam-

legal affiliation, and for the Liberal Arts College, in which case we control for departmental affiliation.

Table 2 lists the unexplained salary differentials (the coefficients for *SEX*) by year for all the faculty employed in that year (Full Sample) and for those hired in the preceding three years (Recent Hires). Note that the recent hires group includes all those recently hired rather than only those hired at entry level positions. We report the differentials for the two alternative measures of the dependent variable, *SAL* and *LNSAL*. Thus, we have estimates of the average salary difference in both dollar and percentage terms. Though we see a dip in the size of the differential in 1977, the differentials are negative and significant at a 5 percent significance level in most cases. The regressions for the full sample explain between 55 and 70 percent of the variation in the dependent variable, while the recent hires regressions explain a somewhat larger percentage.

Some additional analyses were done to determine the effect of controlling for rank.

The adjusted *R*<sup>2</sup>s increase by 10 or more points, but the full sample sex differentials, while smaller in absolute value (by a factor of .2 to .6), are still significant. The significance of the recent hires differential varies by year and subsample. Thus, even if we assume no sexual bias in rank assignment, controlling for rank does not eliminate the sex differential in compensation. Moreover, it does not eliminate the rise in the salary gap between 1977 and 1982. We also ran the regressions with department heads included, with similar results. Department heads receive significantly higher salaries. Since none of the 64 department heads were female in 1972 and 1977, and only 4 of the 70 department heads were female in 1982, these findings indicate that additional salary discrimination may occur through bias in assignment of administrative positions. We also tested for equality of male and female full sample structures, where the unrestricted regression allowed for different structures. The restricted regression constrained all coefficients to be equal except the intercept; that is, the *SEX* variable was included. We accepted the null hypothesis of homogeneous Liberal Arts structures at a 5 percent significance level, but we rejected the null hypothesis when all the colleges were combined, which suggests that more accurate estimates of the sex differential are obtained when we control for departmental affiliation. Finally, regressions for colleges other than Liberal Arts yield sex differential estimates which are sometimes insignificant or positive, a finding that explains why the Liberal Arts College sex differentials are larger than the full university differentials.

Table 3 reports the unexplained sex differences in salary growth over the periods listed in the first column of the table. The sample sizes (*N*) reflect the number of faculty employed in both years of the period. In addition, we partition the 1977-82 sample into two groups: those employed in 1972, 1977, and 1982 (1972 cohort) and those not employed in 1972 (1977 cohort). The explanatory variables are assigned values according to the starting year of the period. In dollars, female faculty have received smaller salary increases, on average, but the dif-

ference is not statistically significant. Moreover, female salaries have grown faster, on average, than male salaries, and the difference is sometimes significant. The results for the 1977–82 period suggest, however, that only the cohort of female faculty present in all three years benefited from the more-rapid salary growth. Nevertheless, the growth was not sufficient to eliminate the sex differential. For the cohort of faculty present since 1972, the unexplained sex differential in 1982 is –6.6 percent and is statistically significant.

### III. Conclusions

We have found that, after controlling for a limited set of individual characteristics, female faculty at the University of Arizona are paid less than male faculty. These differences persist over time. Yet, we find that for those women who were present at the university over the entire period studied, the gap has not worsened. In fact, female salaries grew at a higher rate than male salaries. Thus, it appears that most of the differential in salaries is due to the treatment of females at the time of hire. (Our recent-hires regressions also reflect this.) This is a curious result, since it is precisely at the time of hire, when individuals are most mobile, that there is least opportunity to discriminate. The university must pay competitive market salaries to new hires—any differential at this point must be due to differences in unmeasured qualifications (productivity) and/or discrimination in the market-at-large. One possible explanation for lower starting salaries could be that due to implementation of affirmative action plans nationwide, highly qualified women are hired in preference to highly qualified men by the most prestigious universities and by industry. This leaves a

pool of applicants for the remaining institutions in which women are relatively less qualified than men. Alternatively, the salary and turnover differentials we observe could reflect the university's lack of commitment to sex equity in faculty recruitment, promotion, and retention.

Both the market sorting and lack-of-commitment explanations support the rather unsettling conclusion that the salary differences represent quality differences. Their implications regarding compliance with nondiscrimination legislation, however, are quite different. The explanation that the differentials reflect discrimination in the market-at-large still remains. This explanation is certainly consistent with the findings of others. It is also consistent with our finding that the salary differential dipped in 1977, only to rise again in 1982. In response to 1972 legislation threatening to deny federal program funding to institutions guilty of sex discrimination, universities across the country adopted affirmative action programs and sought to hire more women faculty. By the late 1970's, however, the clamor appeared to have subsided. Although our results suggest little response to the legislation of the early 1970's by 1982, recent actions at the University of Arizona are encouraging. The administration voluntarily awarded women faculty \$300,000 in salary adjustments for 1985.

# Sex Role Socialization and Labor Market Outcomes

By MARY E. CORCORAN AND PAUL N. COURANT\*

It is well known that women earn less than men. The causes of the wage gap, however, are not well understood. Each of the three major economic explanations of the wage gap—human capital, pure discrimination, and “crowding”—suffers from serious shortcomings. The human capital explanation is simply not supported by the data: sex differences in experience, training, and work history can account for only about one-third of the wage differences between men and women. (See Corcoran and G. J. Duncan, 1984, and references cited therein.) Pure discrimination (especially to the tune of about 25 percent of male wages) is just not sustainable in a competitive market (Kenneth Arrow, 1972a, b). And although women are very much crowded into a relatively few occupations (Barbara Bergmann, 1974), this fact does not carry with it an explanation of how and why it comes to be true.

Socialization and discrimination are the two explanations of the unexplained portion of the wage gap that are most often identified (see, for example, D. J. Treiman and H. I. Hartmann, 1981), but the discussion usually stops there. Our purpose in this paper is to begin to look explicitly at how socialization might work in a model of the labor market, how socialization and discrimination might interact, and how one might test empirically for labor market effects of socialization.

## I. Socialization

In an extensive review of the literature, J. P. Eccles and L. W. Hoffman (forthcoming) suggest that sex differences in socialization might affect occupational behavior in at least four ways. First, socialization may

lead women to be more fearful or more anxious, or less confident than men are (the “fear of success” syndrome). Second, sex role socialization may directly affect workers’ skills and personality traits. Some researchers argue, for instance, that girls are encouraged to be more dependent, more person-oriented, and less able mathematically than are boys. Third, children may internalize traditional notions of sex roles, accept these cultural sex stereotypes as fact, and eventually choose occupations that conform to these stereotypes. Fourth, sex role socialization may affect the values men and women attach to different activities so that workers of both sexes tend to value “sex-appropriate” activities. Thus, women may value person-oriented tasks more than men do, even if there were no sex differences in ability to perform such tasks.

The first two sets of phenomena are really human capital arguments. In both cases, women differ from men in ways that might reduce these women’s potential value in the labor market. Such sex differences in human capital may or may not have been caused by discrimination. The third and fourth findings suggest that equally qualified men and women may evaluate the same job characteristics quite differently when choosing jobs. They are thus “taste” explanations when considered from the perspective of the labor market.

## II. Modelling Strategy

If we are to be able to distinguish among various kinds of discrimination and socialization as explanations of male-female pay differentials, we need a model that allows for a variety of possibilities and interactions among them. Given our introductory discussion, such a model must include the following: 1) labor market discrimination against women; 2) socialization of women that tends to lead women to value occupations and jobs that are viewed as “traditionally female” in

\*Institute of Public Policy Studies, 1516 Rackham Building, University of Michigan, Ann Arbor, MI 48109.

character; 3) phenomena (including socialization of employers and customer and co-worker prejudice) that lead employers to value a workplace in which roles are performed by employees of traditionally appropriate gender; and 4) interactions among 1), 2), and 3).

We place one more requirement on a model that purports to shed some light on the issue of how it is that women come to be paid so much less than men. The model must account for the fact that there is a great deal of heterogeneity in the tastes and socialization of workers of both sexes. Thus a convincing account of what is going on cannot depend on the notion that all women, or all employers, have uniform views on the sex appropriateness of different occupations. Further, to the extent that there are employers who do not discriminate in any way on the basis of gender (and surely there are), any elements of a model that depend on employer discrimination must explain why the competitive process does not cause such behavior to disappear.

Throughout this discussion, we assume that the labor market is competitive in the sense that no one possesses monopoly or monopsony power, and that markets for all types of labor are "thick." We assume that individual workers (or potential workers) have utility functions that are defined on income ( $Y$ ), leisure ( $L$ ), and attributes of their job (a vector  $Z$ ). Further, we define a function  $F(Z)$  that maps the vector  $Z$  into a vector of indexes of traditional sex appropriateness for each element of  $Z$ . The more consistent with traditionally female roles, the higher the value of any element of  $F$ . Thus, for any worker  $k$  employed in job  $j$ , the utility function is

$$(1) \quad U_k = U_k(Y, L, Z^j, F^j(Z^j)).$$

Worker  $k$ , of course, will be in that job  $j$  which maximizes (1) subject to the set of jobs and associated wages available on the market. Worker  $k$  may not care about the vector  $F^j$ , but then again he or she may care about it. On average, the partial derivatives  $\partial U / \partial f_i$  (where  $f_i$  is an element of  $F$ ) are positive for women and negative for men. Note that attributes of the job may include such elements

as the sex ratio of current employees, the extent of perceived co-worker prejudice, and the degree to which such prejudice would directly affect the worker.

Sex appropriateness may also matter on the demand side of the labor market. Thus the wage offered by employer  $m$  to potential employee  $k$  will depend on  $k$ 's human capital characteristics ( $Z^k$ ), the attributes of the job, and the vector  $F^j$ . Thus, for employer  $m$  considering employee  $k$  in job  $j$ , the offered wage is

$$(2) \quad w_m^{kj} = w_m(Z^j, F^j(Z^j), Z^k).$$

Again, employer  $m$  may care about elements of  $F^j$  or may not, and may also be affected (following Arrow) by co-worker and customer prejudice, even if the employer himself (herself) has no prejudice.

In a perfectly competitive market, direct employer discrimination will not be sustainable, although if it is difficult for employers to identify prejudiced workers, and if such workers are less productive when they work with the objects of their prejudice, it is still possible that employers would systematically pay one sex less than the other in certain jobs, even if the human capital characteristics of employees were identical.<sup>1</sup> Any differences in wages as a function of gender other than those attributed to co-worker discrimination would be due to differences in employee tastes. If (following the psychological literature cited above) jobs with attributes that are valued by women more than by men are relatively scarce, then it is easy to tell a story consistent with Bergmann's crowding hypothesis that would explain why jobs that are largely filled by women pay less (for a given vector of measured human capital attributes) than jobs that are mostly filled by men. All that is occurring is market equilibrium with a compensating wage differential. Moreover, to the extent that co-worker discrimination affects wages by tending to

<sup>1</sup>The proof of this and other assertions that are not proved in the text due to the limitations placed on the length of this paper are available from the authors, as are the data sources.

reduce the supply of women to jobs where co-workers would hassle women, but where output would be unaffected by sex integration, crowding of women into occupations where they were not faced by such behavior could also be interpreted as yielding compensating differentials—the overt discrimination is not on the part of the employer.

Formal models of the labor market that use (1) and (2) as building blocks can be used to analyze a large number of ways in which prejudice, socialization, and discrimination can interact to produce wage differentials by gender. One interesting version of such a model involves employee search over jobs, and under conditions of costly search leads to the possibility that perceptions of discrimination (whether real or not) can interact strongly with tastes on the part of employees regarding sex appropriateness in ways that can lead to large equilibrium wage differentials. Here equilibrium means that it will not be rational for a woman, earning typical women's wages in a traditionally female line of work, to search for work in the male labor market, where wages are higher, but so is the probability of being hassled on the job, being uncomfortable with performing gender-inappropriate activities, or simply being denied serious consideration for the job.<sup>2</sup>

The value of models constructed along these lines lies not in the fact that they yield any startling new predictions, but in the fact that they provide a notation in which it becomes abundantly clear that at the level of "standard" human capital earnings functions, explanations of male-female wage differences that are based on differences in employee tastes for job attributes are indistinguishable from explanations that are based on employer (or co-worker) discrimination. It is fairly easy to write down models in which

lots of potentially important factors interact, but if we are to find out which of these factors are important in the labor market, we need empirically testable implications of (say) socialization-based stories that are different from discrimination-based stories.

### III. An Empirical Research Agenda

The ideal way to disentangle the possibilities implicit in the above discussion would involve following a panel of children over time and examining how their family environments and their school environments affect their sex-role attitudes and aspirations; how families, schools, attitudes, and aspirations influenced decisions about investment in education and training; and how families, schools, attitudes, aspirations, and human capital affected job choice and wages. At key decision points (choice of college major, first job, etc.), we would need to ask detailed questions about the factors which influenced those decisions—particularly about paths not taken. We know no data that would allow us to take this approach.

We can, however, derive some estimate of how powerful socialization effects might be by looking at specific indicators of socialization and seeing how these fare in the labor market. For instance, a key feature of a socialization explanation model is that sex-role patterns learned in childhood socialization will affect adult economic behavior. Psychological studies have identified the following as family factors which promote sex-role differentiation among children: being raised in a female-headed household, being raised in family with children of one sex, having nontraditional parents (see Eccles and Hoffman; M. M. Marini and M. C. Brinton, forthcoming, for summaries of this research). We are currently using data on 800 young women aged 25–30 in 1981 to test directly for a link between such family factors and young women's market outcomes. These data are taken from the Panel Study of Income Dynamics (PSID), a 14-year (1968–81) study of a nationally representative sample of American families. These young women were children aged 12–17 in their parents' homes in 1968 and had established their own homes

<sup>2</sup>Note that not all women have to have the same perceptions or tastes regarding gender appropriateness. All that is required to get average differences in pay is that women on average value traditional female roles more than men do, and dislike discrimination and hassle from co-workers.

by 1981. We are also using a sample of brother-sister pairs from the PSID to isolate families that maximize similarity (dissimilarity) between brothers' and sisters' labor market outcomes. Using these outliers, we will try to identify family factors that account for this similarity (dissimilarity).

Even if these PSID analyses establish a link between family factors and young women's labor market outcomes, they will not provide much information about the processes by which family factors affect economic outcomes. The PSID provides virtually no data on sex-role attitudes—and a key prediction of socialization models is that women who value traditional roles will be more likely to choose "female" jobs. We will use the General Social Survey (GSS), a nationally representative cross-sectional data set with excellent measures of sex role attitudes, to test whether such attitudes influence women's labor supply, occupations, and wages independently of education and training.

A third source of data, the Thornton Longitudinal Study of Families, has much richer detail on both family background and attitudes for a sample of 906 mother-child pairs from Detroit over the period 1962–80. This study has six waves of data and provides extensive information about mothers' sex-role attitudes (measured 3 times between 1962 and 1980), mothers' work histories, the household division of housework, children's sex-role attitudes in 1980, children's test scores and schooling, and children's aspirations and early labor market outcomes. We plan to use these data for a more complete explanation of how family factors affect children's sex-role attitudes, aspirations, educational choices, and labor market outcomes.

Another way to examine women's occupational preferences is to look at the household division of labor in families where wives have higher predicted earnings than do husbands. In such a situation, it would make more economic sense for men to drop out of the labor force for childrearing than women. We have identified such families in the PSID and are examining their allocation of time between home and market.

The above research projects are only a beginning in an attempt to sort out the ways

in which sex role socialization influence the supply side of the labor market.<sup>3</sup> As we have said above, we are convinced that empirical work that does not examine the mechanisms whereby men and women both behave differently and are treated differently are unlikely to tell us much that we don't know already. That is, women earn less than equally qualified men do, and this gap is caused either by discrimination or socialization.

<sup>3</sup> We think it is equally important to look at demand-side behavior.

## Pacific Protagonist—Implications of the Rising Role of the Pacific

By STAFFAN BURENSTAM LINDER\*

Rapid economic growth in the Pacific region is transforming the world. It is interesting to speculate on the multidimensional consequences, concentrating on the economic and political effects.

Different definitions of the "Pacific" may be adopted, depending upon the problem at hand. To direct attention to a new phase in the grand historical process of changes in the economic and political gravity of the world, it may be suggestive to note how the ratio of Pacific *GDP* to Atlantic *GDP* has increased from less than 40 percent in 1960 to almost 60 percent in 1982. In the Pacific Basin is then included the market economies of the Asian-Pacific region plus China and the five Pacific states of the United States. The Atlantic Basin includes the European OECD countries and the eighteen Atlantic states of the United States.

If we, to analyze the mechanics of this process, concentrate on the market economies of the Asian-Pacific region, we can see that, over the same period, this region's share of world *GDP* has doubled and now stands at over 16 percent. This Asian-Pacific group includes Japan—with 60 percent of the region's *GDP*—and the other members of Northeast Asia (South Korea, Taiwan, and Hong Kong), the ASEAN countries (the Philippines, Indonesia, Singapore, Malaysia, Brunei, and Thailand), and, finally, the South-Pacific countries (Australia, New Zealand, and Papua New Guinea).

\*Stockholm School of Economics and Parliament of Sweden, S10012 Stockholm, Sweden. I thank the Marianne and Marcus Wallenberg Foundation for support and the Hoover Institution for facilities. Some assistance was given by the World Bank.

The gravity shift is also reflected in trade flows. Asian-Pacific exports as a share of world exports have gone from 9 percent in 1960 to 19 percent in 1983. This rise has been managed in spite of the fact that the region has a small part of oil exports, the enormous value increase of which dwarf many changes in the world trade pattern. If we look at manufactured exports, we can see that of all such exports from *LDCs* as much as 59 percent now comes from the four small Asian-Pacific newly industrialized countries *NICs* (South Korea, Taiwan, Hong Kong, and Singapore). This percentage was 25 percent in 1960. Trade changes can also be highlighted by pointing out that U.S. total trade (exports plus imports) with the Asian-Pacific region has risen from less than 50 percent of U.S. trade with OECD Europe in 1960 to 120 percent now.

In trade, the Asian-Pacific countries already match the United States and Europe. In production and income, they are still considerably smaller with the United States and Europe each representing about 30 percent of world *GDP*. However, with the same growth rate differences in years to come, they would reach the same level of *GDP* as the United States and Europe by the turn of the century. If China, now implementing some growth conducive economic reforms, would approach the Asian-Pacific market countries and attain greater economic weight, the importance of the region would become even more pronounced. But, even with the great increase that has already taken place in the relative importance of the Asian-Pacific group of countries, the outward appearance and the inner nature of the world economy and world politics has changed. This transformation is reflected in many ways.

### I. The Demonstration Effect

To begin, there is the *invigoration effect*. It has been vitalizing for less developed countries and also for public opinion in industrial nations to see that growth can be achieved also by those countries which are behind. There was much development optimism in the period immediately following World War II, and then much disappointment, as the strategies in vogue proved unhelpful. For less developed countries, the takeoff proved much more difficult than first thought. But now, when Asian-Pacific LDCs have proved that it can be done, there is some cause for renewed optimism—granted that the previous ways can be changed.

The Asian-Pacific LDCs have demonstrated that the Japanese miracle is not a miracle as it can be duplicated. There is not just a center and a periphery in some eternal arrangement, as is sometimes concluded from the failures of many. The Asia-Pacific LDCs and their success have shown that to take such a position is to abdicate into self-fulfilling pessimism, easy excuses, and facile accusations. Indeed, as the Asian NICs have demonstrated, it is possible not only to stage vigorous growth but to challenge the old industrial countries and even, as Japan, to reach out for leadership. The Asian-Pacific region radiates confidence and instills confidence.

An important question is, then, through which means has Asian-Pacific growth been achieved? There are many different interpretations. However, the more widespread successful growth has become in the region, the more emphasis has been given the economic explanations. Growth accounts stressing institutional factors like the Japanese ethos, the activities of the Japanese Ministry of International Trade and Industry (MITI), Confucian values, Chinese industriousness, abundant natural resources, or the reverse, that is, a situational imperative in the form of nonexistent natural resources may well be important, but they cannot provide the gist of the story. Their relevance differs widely from one country to another in the Pacific region which, it must not be overlooked, is composed of countries diverse in almost all respects,

All the successful countries in the region have, however, one characteristic in common: they are market economies relying on private entrepreneurship and property. Incentives and efficient allocation are emphasized. Foreign trade is given a prominent place in an outward orientation of the development strategy. In short, these countries are capitalist and not socialist. The socialist countries of the region have met with little success.

It may also be noted that in South Korea and Taiwan, growth did not really start until around 1960 when, in both countries, there was a far-reaching redirection of the economic policies away from regulation and interventionism over to a reliance on market mechanisms.

The success of the Asian-Pacific market economies was unexpected and went for a long time unnoticed, as the attention was concentrated on countries pursuing very different economic policies following the once fashionable growth strategies of planning and inward orientation. Explanations stressing the importance of the market system and capitalist methods in the development of the Asian-Pacific countries have now gained wide currency. This will yield what we may call an *ideological effect*. Political thought and economic thinking will be influenced in the old industrial countries where the faith in the system, which once brought these countries their wealth, is again rising after a long period of erosion. It will affect the non-socialist part the Third World where the market system has mostly been downplayed, or has been in disrepute as market signals have often been so overburdened by the effects of extensive regulations that they have failed to give efficient solutions. Finally, the communist countries will find their situation sharply changed by the success of the Asian-Pacific countries.

There are double problems for the communist countries. Their power has diminished relatively when the economic resources of the Asian-Pacific countries, especially Japan and the NICs, have risen so fast. Secondly, the attractiveness of the communist system, as such, has declined. The communist parties in the Asian-Pacific region languish through the combined result of

the nonperformance of the socialist model and of the achievements under capitalist methods. In spite of a considerable military buildup, Soviet political influence in the region is much smaller than it once was. Indeed, in Asia where, according to Nikita Khrushchev, the world battle for the masses would be won, the position of communism has deteriorated sharply.

The success of the market-oriented countries of the Asian-Pacific region will have an effect not only on thinking but also on acting. The ideological effect will be followed by an *imitation effect* in economic policy. At least in some older industrial countries, market solutions will be tried again more confidently. Among the *LDCs*, there will be some attempts at deregulation. In some of the communist countries, economic reforms will be experimented with because of domestic failures in the socialist East, but will be given direction by the success achieved in the capitalist Far East.

The economic reforms presently undertaken in China are at least to some extent inspired by the demonstration effect of successful economic policies instituted by neighboring countrymen. For China not to slide into giant insignificance, it has been important to try some similar methods. In discussions with people who are active in the Asian-Pacific region, it is easy to get confirmation of the view that there has been and is such a demonstration effect at work. Yet, in the literature on Chinese economic reform, there is no reference to such a demonstration effect. One reason for this is that, given the limited scope for debate in China, there are few or no public references to the examples set by neighbors.

There may well be strong policy reversals in China when some of the reforms unavoidably dilute the central power of the communist party. However, even so the on-going reform activities and the prospect of their success has jolted the position of the Soviet Union as dramatically as the defection of China from the Soviet fold once did. Furthermore, the Chinese reforms in their turn have a strong effect on Third World countries that have found it possible to neglect the economic policies and achievements of the Asian *NICs*. For various reasons these

*NICs* have a weak standing in the politics of the *LDCs*. The politics of Taiwan and Hong Kong are both intimately connected with that of the Peoples Republic of China, Singapore is small and South Korea politically exposed because of its conflict with North Korea. Furthermore, the strong political interests elsewhere, fearful of the ideology effect and dreading the imitation effect, have gone to great lengths to denigrate these market economy superstars. The achievements of the Asian *NICs* are explained away as special cases and attributed a number of negative side effects. These countries have a public relation image far below their performance picture.

## II. A Growth Pole Effect

The Pacific dynamism will make this region serve as a growth pole. There will be a *propagation* effect as set out in international trade theory. The Asian-Pacific countries will be a bigger market, serve as a better source of supplies, and add to international factor movements. The successful trade-oriented development strategy will then benefit not only the Asian-Pacific countries, but also their trading partners. This is an important effect in a sluggish world economy.

It is evident that the trading partners of the Asian-Pacific countries will primarily be those countries which have an open, outward-oriented system themselves, that is, the market economies. It is easy to see in international trade statistics this intensification in exports and imports. Especially for the United States, the proportion of exports which goes to the Asian-Pacific countries has risen fast—from 13 percent in 1960 to 25 percent now.

## III. A Threat Effect?

The trading partners will however be exposed to certain difficulties of transition. Gains from trade and from factor movements are not automatic, as they are assumed to be in the simplest trade models. For the gains to be fully realized, there must be a reallocation of factors of production and, in practice, such a reallocation may be painful to those exposed to the need for it.

The forces of competition are required to bring about a beneficial reallocation. They also give dynamic trade gains, as they stimulate the search for improvements and innovation. Yet, those exposed to these pressures often resist them and seek support in cries for protection. As we know, the authorities sometimes yield to the lobbies and, to the cost of the overall economy, put in place tariffs and nontariff barriers or subsidies to help the ailing sectors. Over the last few years, the protectionist pressures have intensified, the undertakings in international agreements have been increasingly disrespected, and it has been difficult to negotiate mutual concessions. The newcomers—and they are primarily the Asian-Pacific countries—have been blamed for posing a severe threat to the old industrial countries.

To evaluate the *threat effect* of Asian-Pacific growth, we may first draw upon the numerous studies that have shown that competition from Japan, the *NICs*, and the *LDCs* in general has not added as much to the pressures for adjustments as usually argued. Other factors such as technological change, demand shifts, and changes in energy prices have necessitated additional adjustment. Furthermore, a new competitor is a new customer, that is, there is no reason why there should be a net destruction of economic activity or employment opportunities.

Yet, adjustment is required. A new competitor is a new customer, granted that we can supply what the new potential customer demands—this added adjustment burden is the problem. The capacity for adjustment has declined in the old industrial countries at the same time as the need for adjustment has increased. The reallocation requirements caused by the Asian-Pacific countries have been added to a total of pressures which has outsized the reduced ability to cope with change.

There are many reasons why the ability to adapt to new conditions has worsened. Tax policies and social policies have reduced labor market mobility and the incentives to invest in new skills and positions. Labor market legislation has similarly given a preference to what exists, although it cannot be viable forever. Restrictive practices, negotiated and applied by the unions, have made it harder

to move into new activities and technologies. Macroeconomic policies of accommodation and unconditional government undertakings to pursue policies for full employment have reduced the responsibilities of the labor market partners to negotiate contracts that are compatible with short-term competitiveness and long-run employment. Shackles have been substituted for sticks and carrots.

These problems have, in particular, beset the European countries where there have been a rapidly rising unemployment and a decline in industrial employment and in the capacity to generate new jobs. In this predicament, governments have tried to find an easy remedy in introducing various subventionist policies and protectionist measures. In the United States, misaligned exchange rates during the last few years have given an import surge that has provided excuses of a more conventional sort for an escalation of protectionism. The question then is, whether vigorous growth (in the Asian-Pacific region) combined with a reduced-adjustment capacity (particularly in Europe) gives some sort of a new irrefutable protectionist argument—the “geriatric tariff.” The answer is no.

Protectionist measures, whether of the old type or in the form of novel new tariff barriers (*NTBs*), do not eliminate the disadvantages of a low-adjustment capacity. Indeed, they compound them, by introducing even greater obstacles to change. The policies will fail. When the investments of structural change for the long-run good are not undertaken and resources instead are used to live fully in the short run, there will be an accumulation of structural problems. Adjustment pressures will then surface in the form of reductions in income and demand, and in a reduced pull from export industries and industries of the future. Both households and industry will in this way be exposed to pressures, and more difficult pressures, which could otherwise have been avoided. The wealth of the old industrial countries has been created through successful activities on free domestic and international markets and cannot be maintained by unfreeing those markets.

Free trade like charity begins at home. Free international trade is the extension of free domestic trade to take advantage of an

even wider division of labor and competition in an optimization of resource allocation. Unfortunately, for some time a freeing of international trade has been paralleled by a process of rapidly increasing domestic trade obstacles. There is a point when domestic trade is so regulated that free international trade sends the wrong signals through the domestic economy, and this economy propagates the wrong signals through international trade. In this situation the framework of international trade will crumble. It is suggestive to watch the great difficulties of the Comecon countries to enter into fruitful and long-standing international trade relations. Within the bloc there are enormous difficulties with "planned trade." To try to make different plans meet means to multiply problems that are already unmanageably big. Trade with market countries is made uneasy as the market countries are not prepared to accord most-favored-nation treatment and free-trade conditions to countries where competitiveness is not determined by efficiency, but by government decree and can be changed from one day to another.

When non-socialist countries now devise systems for planned trade and resort to the potentially even more distorting method of subsidizing exports, it is important not to forget these problems. Regulations and subsidies, and measures to countervail the trade effects of regulations and subsidies, are wearing thin the fabric of international trade.

As the theory of comparative costs teaches us, it is not possible for anyone, no matter how vigorous he is, to outcompete others all around, as is sometimes alleged. However, those with a low adaptability will see the gains from producing and marketing innovative products on a world market scale taken by others. Even with low flexibility, however, income levels on average would be higher than those with restricted trade, but would be far below what they could be with more vitality and initiative.

The strength of Asian-Pacific competition does not make refuted protectionist arguments relevant. That the new actors are highly vigorous does not change anything except that it raises the benefits to be reaped by powerful interaction and that it increases the costs of a failure to respond constructively.

Yet, the threat effect of Asian-Pacific growth is very real, even if its nature is not what its proponents suggest. The threat is that the old industrial countries have lost the flexibility needed to grasp opportunities and that they, in the process of trying to preserve what they have created, ruin it by permitting under competitive pressures, destructive policies to multiply. The menace is not the vitality of some, but the sclerosis of others. As argued before, there is an imitation effect of Asian-Pacific growth in that some try to emulate. However, the threat effect arises in that others, rather than imitating what has succeeded, adopt damaging policies.

The specter of the "Yellow Peril" is again raised with the suggestion that, somehow, there could be an inundation rather than a two-way flow of trade and that there is a permissible excuse for raising trade barriers. But, instead of a Yellow Peril, there is a "White Peril." The White Peril arises from a gradual increase in barriers to domestic trade, and from an extension of foreign trade barriers, which together lead to an accumulation of structural problems. The barriers will harm the old industrial countries and endanger the world trading system. The old industrial countries find it convenient to rationalize their new trade barriers by referring to trade obstacles operated by the Asian-Pacific countries.

Market-based Asian-Pacific growth upsets the confidence of the socialist countries in their system and thus creates several political problems for these countries. It ought to have a positive effect on the beliefs of the Western market economies. In fact, there are political problems for the Western countries, too. Exceptionally high growth in the Asian-Pacific region will unavoidably cause a decline in the relative weight not only of communist countries, but also of the Western market economies. However, this decline will be even more pronounced to the extent the faltering response to the Asian-Pacific challenge (i.e., the White Peril) will strain the political system and the social harmony in the old industrial countries. An expanding battery of obstacles to domestic and foreign trade would aggravate the performance. Second, it will put sticks in the spokes of the wheels of export-led growth in the friendly,

and potentially even more friendly, Asian-Pacific region. There is the possibility of these countries being antagonized by being the victims of discriminatory protectionism and of accusations levied by those who use them as scape goats. The political costs of this are considerable for the Western countries that, instead, should be able to gain handsomely from improved relations with these important partners for the future.

Third, a negative Western response in trade policy will scare off those developing countries that are on the verge of imitating the Asian NICs but now find it seemingly hazardous. The former trade pessimism inspired by the development thinking of the 1950's and 1960's has subsided, but only to be replaced by a new export pessimism caused by the widespread protectionism of the 1980's in the old industrial countries. This pessimism—like the original pessimism

—is overdone as, after all, it has proved possible to expand exports considerably. Yet, the new mood has a definite impact on those countries that may contemplate whether they should move from an inward-looking to an outward-looking strategy. This would be damaging, as it would bar the best or only avenue to material improvement. For the West it is also a political problem, as it would push countries away from applying Western economics methods. They would not be attracted into a more cooperative and less antagonistic Third World.

Asian-Pacific dynamism has important implications. The basic message is this: the newcomers provide enormous new opportunities but threaten, politically and economically, those who in the First, Second, or Third Worlds permit political or economic rigidity to dominate the response.

# Is There Need for Economic Leadership?: Japanese or U.S.?

By W. W. ROSTOW\*

There are two reasonably unambiguous definitions of the inherently ambiguous concept of economic leadership. Definition One relates to innovation and leading sectors; that is, the relative primacy of a country in commercializing a new technology and establishing, for a time, a dominant position in a major sector. In that sense, Britain led in the first phase of the cotton textile revolution (say, 1783–1832), and the United States led in the first phase of the mass automobile revolution (say, 1909–29).

Definition Two relates to policy; that is, the assumption of responsibility for the successful operation of the world economy as a whole by a single country. I shall consider later the necessary conditions for such leadership.

The leading sector and policy definitions are partially linked because only an economic power quick off the mark in converting new inventions into profitable innovations is likely to be able to sustain the balance of payments implications of policies of responsible leadership in the world economy.

I shall now respond to the subject of this paper in terms of each definition of leadership. First, the new technologies and their implications for leadership in the innovational, leading-sector sense. By new technologies I refer to the microchip, genetic engineering, the laser, robots, new communication methods, and new industrial materials. Although germinating for some time—and by no means uniform in their timing—I believe historians will date the innovational stage of this technological revolution from, roughly the second half of the 1970's.

Somewhat arbitrarily, I am inclined to regard this rather dramatic batch of innovations as the fourth such major grouping in

the past two centuries.<sup>1</sup> The fourth industrial revolution has some distinctive characteristics as compared to its predecessors. It is more intimately linked to areas of basic science which are themselves undergoing rapid revolutionary change. This means the scientist has become a critical actor in the drama; and the successful linkage of the scientist, engineer, and the entrepreneur has become crucial to the generation and diffusion of the new technologies. The new technologies are also proving ubiquitous, progressively suffusing the older basic industries, agriculture, animal husbandry, and forestry, as well as all manner of services from education and medicine to banking and communications; and they are, in different degree, immediately relevant to the economies of the developing regions, depending on their stage of growth, absorptive capacity, and resource endowments.

For our purposes, the extraordinary range and diversity of the new technologies bear directly on the prospects for leadership by Japan, the United States, or anyone else. I find it most improbable that any one nation will achieve and sustain across-the-board technological leadership in the fourth industrial revolution, or, indeed, leadership in

<sup>1</sup>The first industrial revolution, dated by innovation rather than invention, came on stage in the 1780's and embraced factory-manufactured cotton textiles, good iron made from coke, and Watt's more efficient steam engine. The second starts in the 1830's and becomes an extremely large-scale enterprise in Great Britain and the American Northeast in the 1840's; i.e., the railroad which, within a generation, induced the invention of cheap mass-produced steel. The third comes round about the turn of the century and consists of electricity, the internal combustion engine, and a new batch of chemicals. In their various elaborations they run down to the second half of the 1960's, when the leading sectors of the third industrial revolution decelerate markedly. For further discussion, see my book (1983a especially pp. 54–60; 88–94). Also see my lecture (1984, especially pp. 3–10).

\*Professor of Political Economy, University of Texas, Austin, TX 78712.

a major area such as micro electronics or genetic engineering or new industrial materials. Each such area represents, in fact, a group of highly specialized and differentiated activities. Given the reasonably even distribution of scientific, engineering, and entrepreneurial talent among the advanced industrial countries—and the similar educational level and skills of their working forces—with the passage of time, specialized comparative advantage is likely to be distributed among a considerable range of countries; and one is likely to see a great deal of cooperation and trade in the new technologies, as well as competition. Indeed, if one examines the pattern of joint ventures across international boundaries and the expanding trade in high-technology sectors, the process can already be seen to be under way, despite the somewhat slower start of Western Europe than Japan and the United States in exploiting the new possibilities.

The diffusion of virtuosity in the new technologies will be accelerated by their indirect impact on the developing regions. Over the next decade we are likely to see the new technologies vigorously applied in the motor vehicle, machine tool, steel, textile, and other industries rooted in the longer past. One result of this conversion to high tech along a broad front is that the more advanced developing countries will no longer be able to count on generating increased manufactured exports simply by exploiting their lower money-wage rates. There is a lively awareness of this change in prospects in the Pacific Basin because of palpable Japanese progress in applying the new technologies to the older industries. In consequence, there is intense interest among the newly industrialized countries in acquiring the emerging technologies. The Republic of Korea, for example, is gearing its current Five-Year Plan to the rapid absorption of the new technologies, including quite radical changes in education policy. (For an extended discussion, see my 1983b book.)

Each developing country differs, of course, in both the extent to which the new technologies are relevant and in its capacity productively to absorb them. But, in general,

potential absorptive capacity is higher than relative per capita levels of real income would suggest.

Consider the case of India, a country with an exceedingly low average real income per capita, conventionally measured. The pool of scientists and engineers in India has increased from about 190,000 in 1960 to 2.4 million in 1984 (see Government of India, 1984); and it is sustained by the fact that something like 9 percent of the Indian population aged 20–24 is now enrolled in higher education, three times the proportion twenty years earlier. Taken along with the large absolute size of India's population, this means that India is quite capable of assembling the critical mass of scientists and *R&D* engineers required to solve the kinds of problems increasingly posed by the fourth industrial revolution and its efficient absorption.

The central question is whether Indian society can achieve, over a wide spectrum of sectors, the bringing together in partnership of scientists, engineers, and entrepreneurs which has happened in atomic energy, space, and, to a significant degree, in agriculture. The linkage has not been effectively made in a good many industrial sectors. I would guess that if these linkages began to firm up in one sector after another, the Indian brain drain would begin to reverse.

While the Indian case is rather dramatic, given the country's size and relatively low real income level, the revolutionary expansion of higher education over the past generation is quite typical of the developing world. For middle-income economies as a whole, the higher education proportion of the relevant age group rose from 3 percent in 1960 to 11 percent in 1979. (See World Bank, 1983.) It will certainly take time for these more advanced developing countries to bring about the partnership of scientists, engineers, and entrepreneurs the absorption of the Fourth Industrial Revolution requires. (It is, indeed, taking quite a lot of time in Western Europe and the United States.) But I do believe it will happen; and the process will strengthen the diffusion of technological virtuosity within the world economy.

Now, what about the second definition of leadership, in terms of policies reflecting responsibility for the viability of the world economy? The capacity to lead, in this sense, depends in part, of course, on a nation's proportionate role in the world economy; its relative contribution to global *GNP* and international trade; and the strength of its capital markets and the scale of its international lending. Britain's contribution to global industrial production may have fallen from 32 to 14 percent between 1870 and 1913, its foreign trade from 25 to 16 percent (see my 1978 book); but its large and active capital market, combined with the maintenance of a free-trade policy, permitted Britain to remain an acknowledged leader in the world economy down to World War I.

There was, however, more to it than that. British leadership was only possible because the United States, the major states of Europe, and the component regions of the British Empire by and large conducted their business in ways compatible with London's rules of the game. They did not generally share London's passion for free trade; but that fact did not prevent the relatively easy flow of goods and capital and people and the acceptance of transmission mechanisms which kept the world economy roughly in step with respect to prices and cyclical fluctuations.

At the base of the system was a fundamental, shared agreement in domestic politics; namely, that tariffs apart, there was no realistic alternative to accepting the domestic consequences of the vagaries inherent in a competitive, largely private enterprise global system of trade and capital movements.

The tragic experiences of the world economy from 1920 to 1939 radically altered both the international and domestic aspects of the pre-1914 consensus. At the close of World War II, the United States, conscious of its interwar derelictions and of its extraordinary relative economic strength in a war-damaged world, explicitly accepted responsibilities for economic leadership, including initially high levels of official grants and loans to foreign governments.

The U.S. role was sustained by a widespread consensus on appropriate internation-

al and domestic rules of the game, the latter including the acceptance by governments of responsibility for both the domestic level of employment and the expansion of social services.

Over the past forty years, the relative role of the United States in the world economy has declined with the revival of Europe, West, and East; with the extraordinary surge of Japanese growth; and with the expansion of the developing economies at overall rates averaging higher than those in the advanced industrial economies. As of 1980, the United States contributed perhaps 23 percent to global *GNP*, the figure having declined from about 33 percent in 1950. (The U.S. and Japanese *GNP* data in relation to global *GNP* are from Herbert Block, 1981, pp. 30-32, Appendix Table 1.) The Japanese *GNP* proportion rose between 1950 and 1980 from about 3 to 8.5 percent.

Despite the sharp relative rise of Japan, the capacity of the United States to lead, in terms of my second definition, is evidently still greater than that of Japan; and that capacity is enhanced, as was that of pre-1914 Britain, by the continuing large role of the United States as a capital market. But the fact is that, no more than Edwardian Britain, does the United States command the power to impose its leadership on the world economy. The distribution of effective economic and political power is, in fact, greater now than then.

My interim conclusions, then, are these. First, whether one uses leading sector Definition One, or rules of the game Definition Two, forces are at work tending to diffuse, rather than concentrate, the power to lead. Second, an overwhelming concentration of power in a single country does not appear to be a necessary condition for effective leadership in the world economy, if there is an effective working consensus on economic rules of the game, domestic as well as international. It is here, I believe, in domestic policy that the critical problem lies which led us to focus this session on the question of leadership in the world economy.

The circumstances that emerged in the world economy in the early 1970's broke up

the consensus on domestic economic policy that had emerged after World War II and acquired legitimacy with the historically unique growth rates of the 1950's and 1960's. No viable successor consensus on domestic economic policy has yet emerged. And it is the lack of an effective consensus on domestic policy in Western Europe and the United States which mainly accounts for the rise of protectionism, distorted real interest rates, precarious debt structures, a grossly overvalued dollar, and other pathological aspects of a disheveled world economy. Specifically, international economic policy is likely to remain ineffectual until the West learns how to reconcile relatively full employment (and reasonably high and steady growth rates) with control over inflation, and how to generate and absorb rapidly the technological possibilities inherent in the fourth industrial revolution.

This judgment stems from a particular view of where the Atlantic world stands in the sweep of modern history. For a century now—from, say, Bismarck's first major social legislation in 1883—the central problem addressed in the advanced industrial nations of Western Europe and North America has been, how can we build industrial societies which reconcile efficiency in a world of rapidly evolving technologies with the humane values in which Western culture is rooted? In politics the process often assumed the form of debate and struggle within a zero-sum game which allocated resources as between welfare and private consumption and investment, as between the less affluent and more affluent. It is one of the major achievements of the Western democratic process that this muted form of class struggle proceeded in relative peace, reaching in the decades after World War II a remarkable apogee. The proportion of social outlays rose in seven major OECD countries from 14 to 24 percent of *GDP* between 1960 and 1980 (see *OECD Observer*, 1984)—a truly revolutionary shift.

Since trees do not grow to the sky, the expansion of social outlays at rates higher even than the extraordinary real growth rates of the 1950's and 1960's was bound, in time, to cease. Pressures to contain these outlays

increased sharply with the explosion of oil prices, exacerbated inflation, and high unemployment rates of 1974–80. After three years of remission, a similar traumatic sequence occurred in 1979–80. This time, the recession continued for a further two years, in part due to U.S. domestic economic policy. The *GDP* per capita, which has grown at 3.8 percent per annum from 1950 to 1973 for the advanced industrial countries, decelerated to 2.0 percent for the period 1973–79, and averaged slightly negative over the next three years. Meanwhile, amidst these setbacks the fourth industrial revolution asserted itself on the world scene with its potentialities, challenges, and dangers for those who lagged in its exploitation.

Clearly, the central issue of domestic political life in the West could no longer be defined in terms of the allocation of a bit more or less to social welfare. Two issues, above others, appeared fundamental if the erosion of the social and physical infrastructure of the advanced industrial countries was to be avoided: the mounting of long-term policies capable of reconciling relatively high rates of growth with control over inflation; and the bringing together of scientists, engineers, entrepreneurs, and the working force to generate and absorb efficiently—and across the board—the technologies of the fourth industrial revolution. In my view at least, the former objective requires effective long-term incomes policies, as well as a judicious blend of fiscal and monetary policies. Evidently, incomes policies are essentially political, social, and institutional, rather than narrowly economic arrangements; and much the same can be said of the partnerships rendered imperative by the peculiar character of the fourth industrial revolution.

Looked at in this way, the advanced industrial countries of the Atlantic world are caught up in a transition between the struggle over the allocation of resources that marked the evolution of the welfare state, and the need for sustained communal cooperation if growth and control over inflation are to be reconciled and the new technologies find an appropriate role in their societies. If one pierces the veil of political rhetoric—which is exceedingly slow to change—

one can observe the transition as a halting de facto process in Western Europe and in the United States.

Assuming this view has a reasonable degree of validity, it throws some light on our instinctive feeling that, somehow, Japan is, at the moment, better geared to the tasks of the generation ahead than the major countries of the Atlantic world. From, say, the first ineffectual Factory Act of 1898 (which aimed to protect women and children) down to about 1936, Japanese social legislation followed, with a lag, a sequence not unlike that to be observed in the Atlantic nations at similar stages of growth. (For a brief summary of this sequence, see my 1971 study, pp. 149–52.) But a generation of war, physical destruction, and postwar recovery broke the pattern and forced Japan into a sequence of communal efforts climaxed by its extraordinary surge of growth since the mid-1950's. A lively sense of the communal stake in the continuity of high growth rates helps account for the fact that Japan has, in a sense, already made the transition towards which much of the Atlantic world is moving rather slowly and with some pain; that is, Japan enjoys a quite well-institutionalized incomes policy and has adjusted its institutions with alacrity to the imperatives of the fourth industrial revolution. There are within Japan debates and struggles about the appropriate proportionate level of social outlays and about income distribution, and these could become more acute; but there is also a more solid consensus than in the Atlantic world that these zero-sum contests are less fundamental than the common effort to assure a steadily expanding pie to be appropriately divided.

These qualities render Japan an extraordinarily strong unit in the world economy; but its capacity to lead is restricted by its incomplete acceptance of the trade responsibilities that leadership demands, the still limited, if expanding, capacity of its international capital markets, and, above all, by the lack of consensus on domestic economic policy in the rest of the OECD world.

I conclude, then, that forces at work in the world economy are likely to diffuse, rather than concentrate, leadership over the time

ahead under either of the two definitions with which I began; that such dilute multi-lateral leadership is quite feasible if a reasonably wide consensus exists on the economic rules of the game, both domestic and international; that the United States is in a position to provide, potentially, a higher degree of leadership than Japan; but it is gravely inhibited because it is still caught up in a transition to a new post-welfare-state consensus on domestic economic policy the Japanese have substantially made.

To answer directly the question posed in the title of this paper—the world economy needs the leadership of both Japan and the United States, but, for different reasons, neither is in a position to supply it at the moment and neither can do the job alone.

The extent to which the United States can provide its share of leadership, over the next several generations, will depend substantially on how fast we diffuse the new technologies across the old basic industry sectors as well as agriculture and the services. I emphasize diffusion rather than generation because, by historical accident—including the land grant colleges and the commitment to serve the economy in which they are rooted—we are almost certainly the best positioned of all the advanced industrial countries to build the close, flexible working partnership of scientists, engineers, and entrepreneurs necessary to create and innovate the new technologies. Indeed, we are in tolerably good shape in three major sectors which arose from laboratories and have managed to maintain the interactive osmotic partnership between scientists and the production process necessary for competitive viability; that is, electronics, chemicals, and aerospace. But our entrepreneurs in steel, motor vehicles, machine tools, and some other basic industries have not worked well with the *R&D* process in the post-1945 years.

I might add that our problem has been compounded by business schools that teach their students how to maximize the bottom line with fixed production functions, but not how to operate in a world of rapidly changing technological possibilities and accelerated obsolescence. And we economists haven't helped much. For more than two

centuries we have failed to build the process of generating and diffusing technologies into the mainstream propositions of macro and micro theory.

Nevertheless, I would guess that with costly time lags, the United States will solve the critical problem of diffusion and meet rather well the challenge of the fourth industrial revolution.

But there is a lion in our path; that is, the four interlocked pathological problems that now have us in their grip: excessively high interest rates, a grossly overvalued dollar, a scandalous balance of payments deficit, and a federal budget deficit running at 5 percent of *GNP*. Sooner or later we shall have to deal with these problems that we are now pushing down the road by borrowing on a profligate scale. The question is whether we can move to a more viable balance without triggering a grave national and international economic crisis.

This is clearly not an occasion to offer detailed policy prescriptions. I would only observe that it seems most unlikely that those now deeply rooted problems will be resolved merely by a somewhat easier monetary policy, a somewhat tighter fiscal policy. I believe at some stage a rigorous incomes policy will be required, not merely to contain the inflationary effects of the necessary dollar exchange rate adjustment, but also to render credible the decline in interest rates and to assist in narrowing the federal deficit.

We have been living grossly beyond our means and we won't get our books into balance merely by a bit of jiggery-pokery with macroeconomic policy.

But I doubt that American political life has the capacity to face these problems until we are in much worse trouble than we are right now. We are more likely to operate on the principle Jean Monnet set out in his *Memoirs*: "...people only accept change when they are faced with necessity, and only recognize necessity when a crisis is upon them" (1978, p. 109).

As an economic historian, I have long rejected the convenient but illusory theoretical distinction between the long run and the short run. The Marshallian long run is moving every day of our lives. Put another way,

the long run is simply the accumulation of what happens over short periods of time. Therefore, there is a clash between my temperate optimism about the United States and the challenge of the new technologies, and my temperate pessimism about our capacity to correct the distortions in our economy without major crisis. A crisis is likely to slow up, for a time, the pace at which we carry forward the fourth industrial revolution.

But looking ahead over the 1980's and 1990's, my net judgment, for what it may be worth, is that Mancur Olson hasn't gotten us yet, that we remain a resilient continental society, with many changing centers of energy and initiative, and that we will sustain a vital role in the economic life of the world economy, as the inevitable and wholesome diffusion of economic power continues as it has since the late 1940's.

But is the diffusion of economic power consistent with leadership and a reasonable degree of order? Or, are we on the road to perpetual chaos in the world economy? On this matter I would supplement my earlier observation on the importance of consensus concerning domestic rules of the game with an institutional recommendation. We are most likely to master chaos in a world of diffuse power by going to work, in the first instance, regionally rather than globally; that the Pacific Basin is a promising arena for demonstration; and the place to start is with the Djakarta initiative of ASEAN of July 12, 1984.

# THE THEORY OF ECONOMIC ORGANIZATIONS<sup>†</sup>

## Human Fallibility and Economic Organization

By RAAJ KUMAR SAH AND JOSEPH E. STIGLITZ\*

Doctrines concerning what is a good way to organize a society have influenced human societies more deeply than any other set of doctrines. Specifically, beliefs that one way of organizing production and exchange is better than others have inspired a number of socioeconomic experiments leading to modern capitalist and socialist societies, with far reaching implications. Yet surprisingly, the central doctrines, though a source of continuing ideological debate, have been the subject of only limited scientific enquiry. The major proposition, the so-called Lange-Lerner-Taylor Theorem asserting the equivalence between competitive capitalist economies and decentralized socialist economies which make use of the price system, made a point in stressing that the issue of the ownership of the means of production might not be central in the comparison of economic systems. The theorem, however, was based on models both of capitalism and of market socialism in which the most important differences between the two systems were suppressed.

This paper describes a research program attempting to delineate some of the critical differences among alternative forms of economic organization. We contend that central to an understanding of these differences is an understanding of differences in the organization of decision making; of who gathers what information, how it gets communicated and to whom, and how decisions get made, both concerning what actions to take and who should fill decision-making positions. This

view should be contrasted with the traditional economic paradigm in which decision making plays no role: the manager, for instance, simply looks up in a book of blueprints what the appropriate technique of production is for the given set of factor prices. In the conventional paradigm, moreover, mistakes are never made, either in gathering or transmitting information, or in making decisions, and indeed, there are no costs associated with these activities. By contrast, the view we take here is that "to err is human," and that different organizational systems differ not only in what kinds of errors individuals make in them, but also in how the systems "aggregate" errors. As a result, organizations differ systematically in the kinds of errors they make, and thus in their overall economic performance. Organizations also differ in the costs associated with information collection, with information communication and processing, and with decision making. Indeed, as we discuss below, perfect decision making can be achieved by arranging enough decision makers in an appropriate manner, no matter how fallible the decision makers are, provided their decisions are not purely random (or worse). What prevents perfect decision making is the cost.

We refer to the specification of the structure of information gathering, communication and decision making as an organization's *architecture*. The objective of our research program has been to construct stylized models of an economic organization within which the consequences of alternative organizational architectures can be examined.

Using these models, not only can we compare the performance of particular organizational forms but we can also ask, given a particular set of objectives and circumstances, what is the optimal structure (within

<sup>†</sup>*Discussants:* David Kreps, Stanford University; Paul Milgrom, Yale University.

\*Yale University, New Haven, CT 06520, and Princeton University, Princeton, NJ 08544, respectively. This is a shortened version of our working paper (1984a).

a class of structures); for example, what is the optimal number of levels in a hierarchy. We have constructed both a positive and a normative theory. Thus our approach allows us to assess the validity of many of the traditional claims concerning the merits of alternative systems.

### I. The Basic Model

To illustrate the basic principles at issue, we present the simplest possible formulation. Consider an organization facing the problem of choosing among a large number of available projects that are of two types: good projects with an expected return of  $x_1$  and bad projects with an expected return of  $-x_2$ . A fraction  $\alpha$  of the projects are good. With perfect information, all good projects, and no bad projects, would be undertaken. A decision maker makes a judgment about whether the project is good or bad based on whatever information he has. We assume that the information available to one decision maker cannot be fully communicated to others. Here we represent a polar form of this "limited" communication such that individuals within any organization convey to one another only whether they judge a project to be good or bad, even though they might have more information at their disposal.

All decision making is imperfect; we assume that the probability that a decision maker judges a good project to be good is  $p_1 < 1$ , and that the probability that he judges a bad project to be good is  $p_2 > 0$ ; the fact that there is some filtering is reflected in  $p_2 < p_1$ .

We consider two different organizations, each consisting of two individuals. In a *polyarchy*, each individual has the right to accept a project and projects rejected by one are evaluated by the other. Thus, the probability that a good project is accepted is  $p_1$  (the probability of acceptance in the first evaluation) plus  $(1 - p_1)$  (the probability of rejection in the first evaluation) times  $p_1$ , the probability of acceptance in the second review. The probability that a good project is accepted is thus:  $f_1^P = p_1(2 - p_1)$ . Similarly, the probability that a bad project is accepted

is:  $f_2^P = p_2(2 - p_2)$ . The (expected value of the) output of the organization is  $Y^P = \alpha x_1 f_1^P - (1 - \alpha)x_2 f_2^P$ .

By contrast, in a *hierarchy*, for a project to be undertaken, it must be approved by both levels of hierarchy; the probability of this for a good project is  $f_1^H = p_1^2$ , and for a bad project it is  $f_2^H = p_2^2$ . The output of the hierarchical organization is  $Y^H = \alpha x_1 f_1^H - (1 - \alpha)x_2 f_2^H$ .

Two results immediately emerge: *polyarchical organizations accept more bad projects* ( $f_2^P > f_2^H$ ); while *hierarchical organizations reject more good projects* ( $f_1^H < f_1^P$ ). The fact that the two systems make different kinds of errors suggests that there will be circumstances under which one or the other performs better. We can ascertain those conditions by comparing the net output of the two systems:

$$(1) \quad Y^P \geq Y^H$$

$$\text{as} \quad \alpha x_1 p_1(1 - p_1) \geq (1 - \alpha)x_2 p_2(1 - p_2).$$

Condition (1) has a natural interpretation. Assume that we conducted two tests of the project simultaneously; projects with both tests turning out positive should clearly be accepted, those with both tests turning out negative should be rejected (otherwise, there would be no reason to run the tests). The question arises what should we do in a split decision. The probability of a split decision for a good project is  $2p_1(1 - p_1)$  and for a bad project it is  $2p_2(1 - p_2)$ . Thus, the expected value of projects with a split decision is  $2[\alpha x_1 p_1(1 - p_1) - (1 - \alpha)x_2 p_2(1 - p_2)]$ . We accept projects with split decisions if their expected value is positive, and reject them if this is negative. But this is precisely the condition (1); if a project would have been accepted with a split decision, there is no point in having a second review; polyarchy is preferable to hierarchy. On the other hand, if a project with a split decision would have been rejected, then the second review is of value: hierarchy is preferred to polyarchy. Second reviews are also of greater value, in this context, when the ratio of bad projects to good projects is larger and when the losses from bad projects relative to the gains from good projects are greater.

There is another interpretation of our result, which becomes clearest when  $\alpha x_1 = (1 - \alpha)x_2$ . Then the condition (1) is equivalent to the condition  $p_2 \leq 1 - p_1$  where  $p_2$  is the probability of accepting a bad project (Type II error),  $1 - p_1$  is the probability of rejecting a good project (Type I error). In this central case, whether a polyarchy is better than a hierarchy depends on the relative likelihood of the decision maker making the two types of errors. (A more general formulation of this problem is examined in our 1984a paper.)

**Committees:** Another type of organizational architecture is a committee. Committees are collections of individuals with well defined rules for decision making (adoption of a project); for example, majority rule or complete unanimity. In a committee with  $n$  members which requires the approval of at least  $k$  members for adoption, the probability of acceptance of a project, for which the individual's probability of a favorable review is  $p$ , is  $f^c(n, k, p) = \sum_{j=k}^n \binom{n}{j} p^j (1-p)^{n-j}$ .

There is a formal similarity between a polyarchy and a committee in which only one individual needs to approve a project for it to be undertaken, and between a hierarchy and a committee in which all individuals in the committee need to approve the project. In our 1984b paper, we have examined the optimal size and decision rules for committees, and show, for instance, that for fixed  $n$ , output is a single peaked function of  $k$ ; and that, for the symmetric case ( $\alpha x_1 = (1 - \alpha)x_2$ ), whether more or less than a majority consensus should be required depends simply on whether  $p_2 \geq 1 - p_1$ .

## II. Complex Organizations

It should be apparent that most organizations are not one of the pure forms (hierarchy, polyarchy, or committee) discussed above, but rather a mixture of organizational forms. We can build more complex organizations out of these basic building blocks. Consider, for instance, a polyarchy of hierarchies in which to be approved, a project must receive the approval of at least one of several decision units; but each decision unit is, itself, a

hierarchy. This corresponds, rather loosely, to a market economy. If each unit has  $n$  hierarchical layers, and there are  $m$  such units in a polyarchy, the probability of a type  $i$  project being accepted is  $f(n, m, p_i) = 1 - (1 - p_i^n)^m$ . By an appropriate choice of  $n$  and  $m$ , we can ensure that  $f(n, m, p_1) > p_1$  and  $f(n, m, p_2) < p_2$ ; that is, the  $(n, m)$  polyarchy-hierarchy accepts more good projects and rejects more bad projects than a single decision maker. Moreover it rejects more bad projects than the simple polyarchy (for which  $n=1$ ) and accepts more good projects than a simple hierarchy (for which  $m=1$ ). We can construct a more complex organization in which the above polyarchy of hierarchies serves as a single unit, and a second level polyarchy of hierarchies is created using such units. With enough such levels to our complex organization, we obtain perfect screening. It is the cost of decision making that prevents perfect decision making. The cost of a multilevel organization rises rapidly with the number of levels, while there is diminishing returns to the increase in expected output. The balance between these two yields an optimal structure to the organization.

The intuition behind why, with enough layers, perfect screening can be obtained is simple. A hierarchy is successful in increasing the proportion of good to bad projects, but only at the expense of throwing out a lot of good projects. In a polyarchy, on the other hand, the stock of projects under consideration is "replenished." In fact, as the number of units in a polyarchy increases, the probability of a project, of any type, getting accepted goes to one. The sense of our result is that if we first filter the set of projects through a hierarchy, and then through a polyarchy, the set of approved projects is more "refined" than what could have been obtained by a single filter; repetition of such a procedure yields perfect selection.

We can use the analysis of complex organizations in the preceding section to prove other interesting results: for instance, if the organizational cost depends only on the number of managers, then *it is better to reorganize a very long hierarchy into two (or*

more) *polyarchies*: and it is better to rearrange a very large polyarchy as two (or more) *polyarchic subunits* within a hierarchy. (See our 1984b paper.)

### III. Selecting Managers: Towards Organizational Dynamics

Among the most important decisions made within any organization are those concerning who will fill what jobs. The fact that such attention is focused on this problem suggests that it makes a difference; individuals differ in their abilities to acquire, communicate, and process information. For each organizational architecture, there is an optimal assignment of individuals with different characteristics. More importantly, the performance of some organizational forms is more sensitive than others to how these assignments are made, and the errors in assignment are themselves functions of the organizational architecture.

The "rules" by which an organization chooses its successors give rise to stochastic processes, describing the assignments of individuals with different abilities to different positions within the organization. We can analyze, say, the steady state of these stochastic processes for various organizational architectures, and compare their relative performance. We illustrate here how this may be done.

Assume that there are two types of individuals, competent (*C*) and incompetent (*I*). Further, suppose that each person in a polyarchy chooses his own successor, whereas the higher level hierarch chooses his own successor as well as that of his subordinate. Clearly, there are four states of a system: (*C, C*), (*C, I*), (*I, C*), and (*I, I*). We can show  $Pr(C, I)$  and  $Pr(I, C)$  are larger in a polyarchy, whereas  $Pr(C, C)$  and  $Pr(I, I)$  are larger in a hierarchy. If the average output of the two systems were the same, any risk averse society would prefer a polyarchy. (For details, see our 1984c paper.)

Alternative economic organizations also differ in their ability to correct selection mistakes. We suspect, therefore, that a still stronger case for polyarchy can be made

once (evolutionary) mechanisms for eliminating deficient organizations are introduced (for example, bankruptcies in a market system).

### IV. Extensions

The formulation presented here ignores three aspects of cost determination associated with organizational design: (a) time (the more levels to an organization, the greater the time required for decision making); (b) communication costs (not only the direct costs of communication, but also the errors which inevitably arise in the process of communication); and (c) the sequence of decision making (for instance, all individuals are assumed to review all projects in a committee, whereas the upper levels in a hierarchy review only those projects which have been sent up to them by lower levels). Since there are costs to review, the sequencing of the review process may have considerable effect on the resources spent on evaluation.

Elsewhere, we have explored these and other extensions of the basic analysis including (a) a more extensive treatment of the consequences of the use of Bayesian decision rules (though, given the information technology of our basic model, our analysis is Bayesian); (b) an analysis of the endogenous determination of the level of expenditures on information acquisition; (c) an analysis of the consequences of alternative organizational forms on the set of available projects (the mix of projects available to an organization itself is an endogenous variable, determined by the incentives provided to those who develop projects; this in turn is partly dependent on the likelihood of projects of different types being adopted, which differ markedly across organizational architectures); (d) an evaluation of alternative organizational forms faced with different problems, for example, choosing the best set of projects, rather than maximizing the expected profit; and (e) externalities. For instance, one organization's decision affects the productivity of projects undertaken by other organizations. Such interactions are important in certain circumstances, and they may strengthen the case for hierarchy.

### V. Concluding Remarks

The differences in the nature of the errors made by different organizational architectures, though important, are not the only differences among organizational forms. We have not examined the widespread belief of a correspondence between economic architecture and political structures; for instance, the alleged correlation between hierarchies and authoritarianism. We have ignored some aspects of organizational comparisons which have already received extensive discussion in the literature. For example, the traditional models emphasize the computational advantages of decentralization (indeed, in some versions, the differences in organizational forms appear to be simply a comparison between alternative algorithms for solving a general equilibrium problem). The fact that the economy solves the problem in "real time" while the models solve for the equilibrium in pseudo time may mean that (at least as traditionally presented) this argument is of only limited relevance.

We have also ignored the problems of incentives, which have been so much at the center of recent discussions of organizational design. We believe these considerations are not only important, but also that the organizational structure may have a significant effect in determining the set of feasible incentives. For instance, when there is more than one decision unit, one can base rewards on relative performance; as the number of units increases, under certain circumstances, a first-best optimum can be achieved. (See Barry Nalebuff and Stiglitz, 1983.) We would argue, however, that organizations may perform badly, not only because of misguided intentions, as stressed in the incentive literature, but also from human fallibility. We have been concerned with showing how even in the absence of incentive problems, individual errors are aggregated differently under different organizational forms, leading to systematic differences in organizational performance.

One argument that can be raised against our analysis is that a hierarchy can always decentralize itself, but the converse is not

true; it thus appears, almost tautologically, that hierarchies dominate polyarchies. Within this perspective, the question we have addressed is, under what circumstances should a hierarchy organize itself polyarchically. But we would argue that this perspective is at best misleading: with the right to intervention within a hierarchical structure goes the obligation to intervene when appropriate circumstances arise, and the concomitant necessity to obtain information to effectuate those interventions. Only if there are hard and fast commitments not to intervene, will a hierarchy be equivalent to a polyarchy. The analysis of these issues must, however, await another occasion.

In this paper we couch most of our analysis in terms of a comparison between alternative economic systems; but our results can be applied at a number of different levels of economic analysis (at the level of a firm or an industry as well as for the economy as a whole). Moreover, our results have direct and obvious implications in the context of political decision making, both for the organization of micro decision making (the rules by which committees should operate, or the managerial processes by which public project selection should be conducted) and for the organization of the state. Indeed, we hope our analysis of self-perpetuating organizations, of the problem that all organizations face in selecting those who are to be in decision-making positions, and the comparative sensitivity of organizational performance to the nature of the selection process, will help put into perspective some longstanding fallacies in political theory concerning the virtues and vices of alternative political structures. Classical discussions of the design of State systems (see Karl Popper, 1950) have essentially ignored the problems arising from human fallibility in decision making. Plato, for example, while arguing for the superiority of aristocratic rule, never considered the problems that would arise in choosing the members of the aristocracy over time, or the consequences (by now all too familiar) of the failure to choose well.

In this paper our objective has not been to present definitive results on the comparison

of economic systems. Rather, it has been to encourage a redirection of attention to what seems to us to be one of the most fundamental issues of economics, and to show how simple models can be constructed which provide considerable insights into some of the longstanding controversies concerning the relative merits of different economic systems.

# Learning from Experience in Organizations

By SCOTT R. HERRIOTT, DANIEL LEVINTHAL, AND JAMES G. MARCH\*

This paper sketches a class of difference equation models for examining incremental experiential learning by economic actors, particularly organizations. The models reflect features of adaptive behavior drawn from observations of decision making in organizations. They picture choice as stemming from decision rules that adjust cumulatively on the basis of trial-by-trial monitoring of the success or failure associated with past adjustments. Such models are in a broad tradition that includes previous work not only in organizational learning and adaptive economics, but also hill-climbing optimization techniques, control theory, and modeling of elementary learning by humans and other animals. Some modest complexities associated with learning are introduced, particularly ways in which learning occurs along several interacting dimensions and within an ecology of learning.

## I. Models of Experiential Learning

We assume a simple choice situation in which a fixed budget is allocated among several alternative, independent activities. Each of the activities provides a return that is proportional to the allocation and the competence (efficiency) of the system at that activity. In the absence of competition, total performance is the potential (or capacity) of each activity weighted by the allocation to that activity and the competence at it, summed over the activities. If  $A_{i,t}$  is the fraction of the budget allocated to activity  $i$  at time  $t$ ,  $k_{i,t}$  ( $0 < k_{i,t} < 1$ ) is the competence

at activity  $i$  at time  $t$ , and  $C_{i,t}$  is the potential return from activity  $i$  at time  $t$ , then  $P_t$ , the performance at time  $t$ , is

$$(1) \quad P_t = \sum_i k_{i,t} A_{i,t} C_{i,t}.$$

Within this choice situation, simple trial-by-trial learning will commonly lead an actor to increase the allocation to activities for which  $k_{i,t} C_{i,t}$  is relatively large, decrease it for those for which it is relatively small.

There are two sets of complications in discovering sensible allocations in this way. The first is that learning occurs along several simultaneous dimensions. Competences and goals adapt at the same time as allocations, and each affects the other. The second complication is that any one learner exists in an ecology of other learners whose actions, goals, and competences affect each other.

## A. Dimensions of Learning

*Adaptive Allocations.* We assume that decision making consists in choosing an allocation ( $A_{1,t}, A_{2,t}, \dots, A_{n,t}$ ) to available alternatives that exhausts the budget. That choice is made by adjusting the previous allocation. The adjustment is made in two steps. At the first step, a proposed allocation to each activity,  $A_{i,t}^*$ , is determined:

$$(2) \quad A_{i,t}^* = A_{i,t-1} + b_1(L_{i,t} - A_{i,t-1}).$$

The learning limit  $L_{i,t}$ , for a proposed allocation to activity  $i$  at time  $t$ , assumes values of 0 or 1 (alternatively 0 and the total budget) with probability  $1 - U_{i,t}$  and  $U_{i,t}$ . Thus,  $U_{i,t}$  is the probability of proposing an increase in the fraction of the budget allocated to alternative  $i$ . The value of  $U_{i,t}$  changes in response to experience, depending on the adjustment in allocation made on the previous trial and the outcome on that trial ( $P_{t-1}$ )

relative to some goal ( $G_{t-1}$ ). Specifically,

$$(3) \quad U_{i,t} = U_{i,t-1} + b_2(1 - U_{i,t-1})$$

$$\text{if } A_{i,t-1} > A_{i,t-2}; \quad P_{t-1} > G_{t-1}$$

$$\text{or if } A_{i,t-1} < A_{i,t-2}; \quad P_{t-1} < G_{t-1};$$

$$= U_{i,t-1} - b_2 U_{i,t-1}$$

$$\text{if } A_{i,t-1} > A_{i,t-2}; \quad P_{t-1} < G_{t-1}$$

$$\text{or if } A_{i,t-1} < A_{i,t-2}; \quad P_{t-1} > G_{t-1}.$$

Equation (3) defines a variation on a standard stochastic learning model. Where  $b_2 = 1$ , the direction of the adaptations is determined without stochastic variation. The two learning parameters,  $b_1$  and  $b_2$ , affect the rate at which adjustments in allocations are made. The adjustment of  $A_{i,t-1}^*$  and  $U_{i,t-1}$  from one trial to the next are proportional to the difference between the current values and the upper or lower limits of those variables. They can also be made proportional to the absolute difference between  $P_{t-1}$  and  $G_{t-1}$ , more specifically to  $[|G_{t-1} - P_{t-1}| / (G_{t-1} + P_{t-1})]$ . In such a case, the adaptations are more finely tuned to the magnitude of success or failure. Another form of fine-tuning would disaggregate performance and goal, associating each with a specific activity rather than to their sum. Moving from  $A_{i,t}^*$  to  $A_{i,t}$  involves satisfying the constraint that the sum of allocation increases in individual activities must equal the sum of allocation decreases while maintaining the relative sizes of individual changes projected by  $A_{i,t}^*$ .

*Adaptive Competence.* Models of adaptive learning (for example, binary choice learning, two-armed bandits) commonly assume that the outcome from a current choice is independent of the history of choices. In many situations of economic allocation, however, it seems more reasonable to assume that competence at an activity decreases with the passage of time and increases with allocation to the activity. Thus,

$$(4) \quad k_{i,t} = (1 - b_3)k_{i,t-1}$$

$$+ A_{i,t-1}b_4[1 - (1 - b_3)k_{i,t-1}].$$

The coefficients of competence decay ( $b_3$ ) and learning ( $b_4$ ) control the rate at which efficiency at an activity responds to disuse and experience. Equation (4) is a variant of a standard learning-by-doing model.

*Adaptive Goals.* We assume that performance aspirations adapt to past performance so that the goal in any time period is a mix between the previous goal and the previous performance.

$$(5) \quad G_t = (1 - b_5)G_{t-1} + b_5P_{t-1}.$$

The result is to make the goal an exponentially weighted moving average of performance, with  $b_5$  determining the relative weight attached to relatively recent performance results. If  $b_5 = 1$ , then  $G_t = P_{t-1}$ ; and the adaptation responds simply to changes in performance. If  $b_2 = 1 = b_5$ , the model becomes a standard hill-climbing procedure.

### B. The Ecology of Learning

*Diffusion of Experience.* In a social environment, learning from direct experience is supplemented by the diffusion of experience, that is, by copying others. From a rational perspective, copying can be seen as a way of increasing (on average) the amount of experience from which an individual draws while decreasing (on average) the linkage between that individual's situation and the experience base of action. From a behavioral perspective, it can be seen as a standard way by which adaptive systems deal with uncertainty and ambiguity.

If we let  $A_{j,i,t}^*$  be the proposed allocation of individual  $j$  to activity  $i$  at time  $t$ , a natural extension of (2) yields

$$(6) \quad A_{j,i,t}^* = (1 - d_1)$$

$$\times [A_{j,i,t-1} + b_1(L_{i,t} - A_{j,i,t-1})]$$

$$+ d_1 \sum_{h \neq j} A_{h,i,t-1} / (n - 1).$$

That is, allocations adapt to the mean allocation made by other actors, as well as to direct experience.

If we let  $k_{j,i,t}$  be the competence of individual  $j$  at activity  $i$  at time  $t$ , a natural

extension of (4) yields

$$(7) \quad k_{j,i,t} = (1 - d_2) \{ (1 - b_3) k_{j,i,t-1} + A_{j,i,t-1} b_4 [1 - (1 - b_3) k_{j,i,t-1}] \} + d_2 \max_h k_{h,i,t-1}.$$

That is, competences adapt to the highest level of competence exhibited within the population of actors.

If  $G_{j,t}$  is the goal of individual  $j$  at time  $t$ , then a natural extension of (5) yields

$$(8) \quad G_{j,t} = (1 - b_4) G_{j,t-1} + b_4 \left\{ \left[ d_3 \sum_{h \neq j} P_{h,t-1} / (n - 1) \right] + [(1 - d_3) P_{j,t-1}] \right\}.$$

That is, an actor's goals adapt to the mean performance of other actors, as well as to her own performance. The adaptation coefficients ( $d_1, d_2, d_3$ ) determine the rate at which allocations, competences, and goals spread from one learner to another.

*Interdependence of Experience.* Where experience is interdependent, the performance realized by any one actor depends not only on that actor's allocations and competences, but also on the actions of others. The interdependencies may involve "mating," in which each actor's rewards for a particular activity are augmented by having other actors engaged in the same activity. They may involve competition, in which each actor's rewards for a particular activity are decreased by having other actors engaged in the same activity. They may involve "hunting," in which the rewards of some actors are increased by the presence of other actors engaged in the same activity who, themselves, have their rewards decreased by the joint presence. In the present paper, we consider only the competitive case. If more than one actor allocates effort to a particular activity, the allocation and competence of each reduces the return for the others. Specifically, in any time period where  $\sum_j k_{j,i,t} A_{j,i,t} > 1$ , the return from activity  $i$  for actor  $j$  is

$$(9) \quad R_{j,i,t} = \frac{(k_{j,i,t} A_{j,i,t})^w}{\sum_{h \neq j} (k_{h,i,t} A_{h,i,t})^w} C_{i,t}.$$

The power  $w$  determines the way in which an overexploited activity is shared among competitors.

*Organizational Subunits.* Many economic actors are organizations—firms, armies, public bureaucracies, schools, unions. Organizations have subunits whose actions affect outcomes and whose rewards are linked to local results, as well as to overall performance. We have modeled organizations consisting in subunits, similarly allocating among activities, while adapting allocation, competences, and goals over time. Since allocations within subunits affect not only the performance of subunits but also the performance of the organization as a whole, organizational learning is heavily interactive. The details are omitted here. They parallel the earlier characterizations of learning but include some additional features to link the learning and performance of subunits with the overall organization.

## II. Some Results

We report here some fragmentary results based on analysis of the determinate ( $b_2 = 1$ ) case involving only two alternative activities with unchanging (but different) potentials. We address ourselves to four general questions relevant to assessing trial-by-trial learning as a form of intelligence: 1) To what extent does incremental learning of this type produce, after a suitably long period of time, sensible adaptations to environmental possibilities? 2) To what extent are long-run outcomes independent of initial allocations, competences, and goals? 3) To what extent is the long-run performance of learners improved by increasing the learning parameters? 4) To what extent is the long-run performance of learners improved by tuning the adjustment of allocations more finely to the magnitude of success or failure?

### A. The Isolated Learner

If adjustment of allocations over time is roughly tuned (i.e., if  $b_1$  is fixed), the isolated learner specializes. That is, an equilibrium is reached at which all resources are devoted to one alternative or the other, and where  $k_i =$

$b_4 A_i / (b_3 + b_4 A_i - b_3 b_4 A_i)$ . Specialization is also characteristic of the stochastic version of the model (i.e.,  $b_2 < 1$ ). Specialization may not involve the superior alternative, however. The equilibrium outcome depends not only on the learning parameters but also on the initial allocation, competence, and goal. In general, as the initial conditions become more favorable to the inferior alternative, the set of learning values that result in specialization at the inferior value expands.

Given initial conditions in which competence in and allocation to an inferior alternative are high, specialization in that activity is likely. It can be avoided by slow adjustment of allocations and rapid adjustment of goals, or by learners whose absolute level of performance declines over time (thus producing failures). With fixed capacities for the two alternatives, the latter result requires that the competence decay rate ( $b_3$ ) be high relative to the competence learning rate ( $b_4$ ), that is, slow learning and fast forgetting.

In the "finely tuned" case, where the adjustment of allocations is made proportional to the absolute disparity between performance and goal, the model also reaches a stable mixture of allocations, competences, goal, and performance; but the allocation does not, in general, reach 1 or 0. Rather, it locates an equilibrium combination at some interior, suboptimal point. Thus, fine-tuning yields higher performance in situations in which rough-tuning leads to specialization in the inferior alternative, but not in those cases where rough-tuning leads to specialization in the superior alternative.

### B. Diffusion of Experience

The effects of diffusion of experience among parallel (but noninteracting) learners depends on characteristics of the population of learners. The discussion here is limited to the case of a population heterogeneous with respect to the values of  $b_1$  and  $b_5$ , but homogeneous with respect to the other learning rates (i.e.,  $b_2 = 1$ ,  $b_3 = 0.1$ ,  $b_4 = 0.5$ ). Diffusion of allocations decreases both the mean and the variance of performance within the population (relative to isolated learners), normally driving all actors to a common set

of allocations, competences, and goals. Diffusion of competence, goals, or both normally increases average performance. In addition, the diffusion of competence changes the region of the parameter space that leads to specialization in the superior alternative, giving an advantage in that respect to learners who adjust allocations relatively quickly and adjust goals relatively slowly.

Goal diffusion, by making goals more homogeneous among learners than is performance, tends to divide a population of non-competing learners into one group with a history of subjective successes, another with a history of subjective failures. Since persistent success produces specialization and persistent failure produces nonspecialization, goal diffusion partitions the population into three groups of actors. The first group allocates all its resources to the inferior alternative; the second allocates all its resources to the superior alternative; the allocation by the third group oscillates around an equal division between the two. The proportion in each group depends on the initial conditions and learning parameters. It also depends on whether the allocation adjustments are finely or roughly tuned, with fine-tuning tending to produce a larger number of learners who fail consistently and thus divide their allocations equally among the alternatives.

### C. Interdependence of Experience

The effects of competition depend on the number of competitors and the parameter  $w$  that controls the way in which the resources in an overexploited activity are divided among competitors, as well as the characteristics of the population of competitors. With small numbers of competitors ( $n = 2, n = 3$ ), specialization is common. In the case of two competitors, this means each competitor specializes in a different activity. Under many, but not all, conditions, the slower learner becomes the specialist in the superior alternative, thus has higher performance. In the case of three competitors, a quite typical result is that one or two of the three specialize, while the other does not. Faster learners tend to become specialists, but whether that results in their also having higher perfor-

mance depends on the alternative in which they specialize and the pattern of allocations by the others.

With larger numbers, both the analysis and the story become more complicated. In general, if  $w > 1$ , rapid adjustment of allocations leads to better performance than slow adjustment; if  $w < 1$ , the converse is true. If the adjustment of allocations is made proportional to the magnitude of success or failure (the fine-tuning option), the system reaches an apparent equilibrium which depends on the initial allocations and competences as well as the learning rates. In the fine-tuning case, moderate rates of goal adaptation often seem advantageous, but not always. There are also numerous situations with relatively idiosyncratic outcomes. In otherwise apparently smooth response surfaces mapping variations of performance onto variations in learning rates, substantial spikes appear.

#### D. Competition with Diffusion

If diffusion and competition are both present, we obtain many of the same basic results observed in the case of either alone. Goal diffusion, however, confounds the general observation that rapid, rough-tuned adjustment of allocations gives an advantage where  $w > 1$ . When goals diffuse, competitors who are persistently successful tend to become specialists in one activity or the other. Fast learners tend to specialize, but the fastest learners often specialize in the inferior alternative, leaving the superior alternative to the their somewhat slower cousins. In addition, variation in performance within the population of competitors tends to be decreased by allocation diffusion, but increased by competence or goal diffusion.

#### E. Organizational Subunits

Over a fair range of situations, the consequence of introducing learning subunits is to make both the intelligence of learning through trial-by-trial adaptation and its analysis somewhat problematic. The interactions

make it less likely that organizations will specialize in inferior activities, but also less likely that they will specialize in superior activities. In this respect, the existence of subunits produces effects not unlike the presence of random error in performance. Although it seems likely that there are regular cycles in the resulting patterns of adaptations, we have not as yet discovered them.

### III. Discussion

To provide a base for considering experiential learning as a form of adaptive intelligence, we have modeled a collection of behavioral observations about the forms of learning common in organizations. Since there is ample experimental and observational evidence for believing that simple experiential learning can be a powerful procedure for improving human performance and since the informational, computational, and coordinative requirements of adaptive intelligence seem to be closer to the capabilities of individual and organizational decision makers than are the demands of anticipatory intelligence, we explore the conditions for sensibility of this kind of incremental adaptation.

Although analysis of the models is very incomplete and much of the structure remains unexplored, we can begin to answer the four questions with which the present discussion began. 1) Learning of the sort we have described leads reliably to optimal choices in some situations, but does not do so in others. 2) Allocations at equilibrium are not determined uniquely by activity potentials, but are extensively dependent on the rates at which adaptations take place and on initial allocations and competences. 3) Although fast learners often do better than slow learners, there are many plausible situations in which slow learners do better than fast learners. 4) Although fine-tuned adjustment of allocations facilitates locating an equilibrium, the equilibria achieved are not reliably better than the long-term results of a rougher-tuned adjustment, in fact, are often worse.

# Informational Structure of the Firm

By KENNETH J. ARROW\*

The modern firm is typically not only large but complex. It has an internal structure, and its parts have to communicate and coordinate with each other. This is hardly a new observation. If you will forgive my use of the English platitude, "it's all in Marshall," let me quote, "the development of the organism, whether social or physical, involves an increasing subdivision of functions between its separate parts on the one hand, and on the other a more intimate connection between them" (Marshall, 1948, p. 241).

The complexity of the firm has of course scarcely gone unnoticed in more recent literature. Alfred Chandler (1979) has given a first-rate account of the evolution of the firm's internal structure in response to changing economic needs. Oliver Williamson and others in the bounded rationality tradition stemming from Herbert Simon have sought to create a theory which will accommodate the observed structures of industry. But the history of economic thought suggests that these theories will only find analytic usefulness when they are founded on more directly neoclassical lines, that is, in terms of individual optimization and equilibrium. I do not regard this point of view as some kind of absolute methodological imperative. I merely argue that it has typically been found most convenient to use whether for theory or as a basis for empirical work, and it is worth while to pursue the viewpoint of optimization to see where it will lead.

Nor will I try to give here a full-scale neoclassical theory of internal structure based on specialization and coordination. Rather my aim is to indicate some serious problems in formulating the interchange of information among the component parts of a firm or, indeed, other organization.

I take as the basic model the theory of teams (see Jacob Marschak, 1953, 1954; Marschak and Roy Radner, 1972). Although this theory is now more than thirty years old, its development has been sporadic. It has had as much influence among control theorists as among economists.

The elements of a firm, in team theory, are *agents* among whom both decision making and knowledge are dispersed. The problem, at least as usually formulated, is that of *design*. It is to determine an allocation of information and a set of decision rules for the individual agents so as to optimize some given payoff function for the firm. The payoff depends on the actions taken by all the agents in the firm and on some environmental factors (such as prices or technological conditions) not known at the time the team is designed. These environmental factors are usually referred to as the *state of the world*. The concept of information for an agent is defined as usual in statistical decision theory or communication theory. Each agent observes a random variable, sometimes termed a *signal*. There is a joint distribution of the state of the world and the signals to all agents, which defines a conditional distribution of the state of the world and of other agents' signals given the signal to any one agent.

Each agent has a set of actions from which choice is to be made. Since the agent observes only the appropriate signal, his or her decision rule is a function mapping the agent's signal to that agent's action space. The design problem properly speaking is then both to choose a signal for each agent and a decision rule mapping that signal into actions. We may call the assignment of signals to agents the *information structure* and the choice of decision rules the *decision structure*.

The choice of information structures must be subject to some limits, otherwise, of course, each agent would simply observe the entire state of the world. There are costs of

\*Stanford University, Stanford, CA 94305.

information, and it is an important and incompletely explored part of decision theory in general to formulate reasonable cost functions for information structures. Indeed, most of the theory of teams to date has concentrated on choosing optimal decision structures for a given information structure, rather than optimizing on information structures, thereby avoiding explicit consideration of cost functions.

Up to this point, the model has assumed an initial distribution of information followed by decisions. In the vast literature on economic planning, emphasis is put on communication. Before action is taken, there is an exchange of information, which may take place many times, infinitely often in fact in the analysis of convergent optimization processes. These can be assimilated to team theory. At each stage, the message for each agent to each other agent is a function of the information available to that agent, which now includes the agent's original signal plus all messages received by that agent in previous rounds. What has only now begun to be recognized is that one has to add to an agent's information all the inferences that can be made from the signal and subsequent messages.

The team model does abstract from one very important aspect of organization much stressed in recent literature, that of incentives. It is assumed that the firm as such has organizational objectives which are adhered to by each member. I certainly do not wish to minimize the importance of incentives to perform. There are two reasons why I accept this abstraction here: 1) I want to emphasize the choice of the information structure, which is still of great importance in models with incentives and has been neglected; these models invariably take the structure as given. 2) The present incentive models take a very limited view of the information structure. In fact, within a firm there are many forms of information gathering ("monitoring," in the usual terminology of principal-agent theory) beyond those in our current models. It may be a good abstraction to regard monitoring within the management structure of a firm as sufficiently complete that shirking is not an issue. It is noteworthy that bonuses are to a

large extent discretionary (i.e., tied to observations that cannot easily be quantified) rather than defined functions of measurable performance variables.

With this lengthy background, let me take up some specific problems in characterizing information and communication in firms. First, I will study Martin Weitzmann's (1974) paper on prices vs. quantities as a team problem, to illustrate the analysis in a simple case. I will also use this example for some reflections on the counterintuitive implications of the much-used quadratic payoff functions. Then I want to consider alternative possible assumptions on the cost of information, including the well-known Radner-Stiglitz (1984) theorem suggesting a non-concavity in the production of information. Finally, I will conclude by resuming some recent developments which illustrate some economies in information transfer when the law of large numbers can be used.

Weitzmann proposed the following simple model of decentralization. There are  $n$  productive units, each of which can produce the same product. The cost function of unit  $i$  is

$$C_i(q_i) = t_i q_i + (c/2) q_i^2.$$

Here,  $q_i$  is the output of unit  $i$ ;  $t_i$  is a signal observed by the unit but not by any other agent. Let  $q$  be total output, so that  $q = \sum q_i$ . Let the benefits from a total output of  $q$  be  $B(q) = aq - (b/2)q^2$ .

The random variables  $t_i$  are assumed independently and identically distributed. Without any real loss of generality, it can be assumed that they each have mean zero. Let  $S$  be the common variance of the parameters  $t_i$ . Weitzmann compares two coordination policies. One is to set an output price; each agent maximizes profits given its cost function. The price is chosen to maximize expected benefits minus expected losses. The other policy is that an output quota be set for each firm. Since the prior information is the same for all units, the quota is the same for all units. Unlike the price policy, there is no feedback from the actual signals at all.

Let  $P_p$  and  $P_q$  be the expected payoffs under the price and quantity policies. Then

Weitzmann shows that

$$P_q = na^2/2(nb + c),$$

$$P_p = P_q + [n(c - b)S/2c^2].$$

The team theory solution is to choose the optimal decision rule relating  $q_i$  to  $t_i$ , instead of confining attention to two kinds of rules, that derived from assuming a price and that derived by assuming no dependence of  $q_i$  on  $t_i$ . Because the problem is quadratic, it can be seen that the optimal decision rules are linear. The optimal rule can be found easily (it is in fact a special case of a very general result in Marschak and Radner, pp. 167-69). It can be shown that the expected payoff to the optimal team policy is  $P_t = P_q + nS/[2(b + c)]$ .

As is obvious from its derivation as an optimal policy and as can be calculated directly,  $P_t$  is greater than either  $P_p$  or  $P_q$ . The optimal team policy always lies between the unit outputs derived from the price and quantity policies. Hence, the Weitzmann problem of choosing between the two extremes seems unnecessarily limited.

When examined closely, there are some peculiar aspects to the variation of the optimal payoff with respect to the number of agents,  $n$ , and the variance  $S$  of the cost parameter. The payoff  $P_t$  increases linearly in  $n$  when there is some variance, and so approaches infinity with the number of firms. The same is true of the expected return to the price policy if  $c > b$ . (If  $c < b$ , the expected return to the price policy approaches negative infinity, even more surprisingly.) It is also true that the expected return under the optimal team policy increases with the variance, though possibly this is less paradoxical. The possibilities of gains from trade increase with the diversity of the units.

In fact, all these counterintuitive consequences spring from the quadratic payoff functions together with the failure to observe nonnegativity constraints on the output variables. I take this result to be a warning about trusting quadratic functions too strongly. The quadratic hypothesis has been common in control theory, as well as the economics of

uncertainty, for its analytic convenience. But for some purposes at least it can be very misleading.

This example has taken the information structure as given. If we want to analyze the choice among information structures, it is necessary to include in the analysis measures of their costs. I will give two examples, with applications, before turning to the general question of concavity of the cost function. The first is the Shannon measure of information. Suppose  $X$  is a random variable with a discrete distribution, with  $p(x)$  as the probability that  $X$  takes on the value  $x$ . Suppose we have the following procedure for identifying the true value of  $X$ : at each stage, the remaining possible values of  $X$  can be divided in any desired way into two parts, and it is possible to identify in which part the true value lies. Then a well-known theorem of information theory tells us that the minimum expected number of stages needed to find the true value of  $X$  lies between  $H(X)$  and  $H(X) + 1$ , where  $H(X) = -\sum p(x) \log_2 p(x)$ , the Shannon measure interpreted as a cost. This technology for determining the true value is not entirely convincing, but at least it is a consistent story. As it stands, it is a measure of the cost of going from a probability distribution to certainty. It may be generalized to yield a cost of going from a distribution to a conditional distribution. Let  $S$  be a signal. If  $S$  takes on a particular value, say  $s$ , let  $H(X|s)$  be the Shannon measure for the conditional distribution of  $X$  given  $S = s$ . Then the average reduction in the Shannon measure of uncertainty is,  $H(X) - E_s[H(X|S)] = R(X, S)$ , defined as the *rate of transmission*. This suggests that the cost of a signal  $S$  be taken as proportional to the rate of transmission with respect to the state of the world,  $X$ .

For an application of this measure, I draw upon some earlier work (1971). Suppose an investor can buy a portfolio of *elementary* securities, that is, each security pays off in exactly one state of the world,  $x$ . Let each security have a price of one dollar per unit, and let  $r_x$  be the payment to a unit security for state  $x$ . The investor has  $A$  dollars to invest. The investor's utility function for terminal wealth is taken to be the (natural)

logarithm. The action is the choice of amounts  $a_x$  to be invested in security  $x$ . Terminal wealth then is  $a_x r_x$ . Hence, the chosen portfolio is that which maximizes  $E(\ln a_x r_x)$  subject to the condition,  $\sum a_x = A$ . Straightforward calculation shows that the optimal portfolio is the choice,  $a_x = Ap(x)$ .

Now suppose the investor has the option of buying any signal  $S$  at a price proportional to the rate of transmission, that is,  $cR(X, S)$  for some constant  $c$ . Assume that the signal must be purchased prior to observation of the outcome, so that the purchase price must be subtracted from initial assets before investment. It is easy to see that if a signal with transmission rate  $R(X, S) = R$  is purchased, then the optimal decision rule is to set  $a_x(s) = (A - cR) p(x|s)$ , where  $s$  is the observed value of  $S$  and  $p(x|s)$  the conditional probability that  $X = x$  given that  $S = s$ . The expected payoff with the optimal policy is,

$$E(\ln r_x) + \ln(A - cR) - H(X) + R.$$

Note that this is a concave function of  $R$ . It is maximized with respect to  $R$  by setting  $R = (A - c)/c$  if  $c < A$ ,  $= 0$  otherwise.

Consider an alternative model for suggesting a cost function for information, namely Bayesian normal sampling. The cost of the information obtained from a sample is taken to be proportional to the size of the sample. For a normal distribution, it is reasonable to take the amount of information to be the reciprocal of its variance, called the *precision*. Let  $X$  be normally distributed with precision  $h_x$ . Consider a sequence of signals,  $S_i$ , whose distributions conditional on  $X$  are normal, independent, and identical. Let the conditional precision of any one be  $h_s$ . The agent has to choose an action  $a$ , with loss  $(X - a)$ .

The agent can observe the first  $n$  signals before performing the action. The value of  $n$  is also subject to choice. If  $n$  is chosen, the precision of the conditional distribution of  $X$  given  $S_1, \dots, S_n$  can easily be calculated to be  $h = h_x + nh_s$ . Since the cost of sampling is proportional to  $n$ , it can also be seen to be linear in  $h$ . If we assume that the cost of sampling is added to the loss due to the

action, it can be seen that the agent wants to choose  $h$  to minimize  $h^{-1} + ch$ , again a concave function. The optimal value of  $h$  is  $c^{-1/2}$ .

Radner and Stiglitz have proved the following remarkable theorem:

Let  $S(t)$  be a one-dimensional family of signals defined for  $t \geq 0$ . The conditional density of  $S(t)$  given  $X$  is  $p_t(s|x)$ , assumed differentiable in  $t$  at  $t = 0$ . Further assume that  $p_0(s|x)$  is independent of  $x$ , that is,  $S(0)$  yields no information about  $X$ . Let  $a(s, t)$  be the action taken if the signal  $S(t)$  has been chosen and takes on the value  $s$ . Let  $w(a, x)$  be the outcome in money terms if action  $a$  is taken, and the state of the world is  $x$ , and let  $c(t)$  be the cost of having the signal  $S(t)$ ; assume that  $c'(0) > 0$ . Finally, let  $V(w - c)$  be the utility function for income. Then the expected utility gain by changing the signal from  $S(0)$  to  $S(t)$  is always negative for  $t$  sufficiently small.

Alexander Pope told us, "a little learning is a dangerous thing." Radner and Stiglitz, a little more circumspectly, tell us that a little information is never worth the cost. This conclusion implies that the value of information is not concave, at least not in the neighborhood of the origin, which corresponds to an uninformative signal. But in our two examples, both certainly reasonable, the value of information was concave in a properly chosen measure. The Radner-Stiglitz theorem is correct mathematically, so that we can be sure that one of its hypotheses does not hold in the two examples. The hypothesis that fails is the seemingly innocuous condition that the likelihood function  $p_t(s|x)$  is differentiable in  $t$  at  $t = 0$ . If we parametrize the signals in our two examples by  $R$  or  $h$ , respectively, then  $p_t(s|x)$  has an infinite derivative with respect to  $t$  at  $t = 0$ .

I conclude by discussing a different kind of subtlety in the use of information. Team theory differs from the classical work on the economics of socialism in several ways, but one is the use of a priori information in guiding the communication and coordination processes. One particular kind of argument that has been developed is to take advantage of the law of large numbers when the agents form a well-defined statistical universe. In a

resource allocation problem, when the center's action is the allocation of some scarce resource among units, the optimal action will in general depend on the productivities of all the units. However, if these productivities can themselves be considered as a random sample from a known distribution and if there are many units, then effectively the distribution in the sample can be regarded as known. Therefore, some information need not be collected, or, more precisely, its value goes to zero as the number of agents approaches infinity. A model of this kind has been studied by myself and Radner (1979), and similar reasoning has been used independently by J. K. Leenstra et al. (forthcoming), though more for the purposes of approximating the solution of nonconcave problems.

These remarks are just a few of the many possibilities which can be invoked in theory to analyze the optimal informational structure of firms. They suggest that the solutions in different circumstances may look very different, even though based on the same maximizing principles.

## INDUSTRIAL POLICY IN FRANCE<sup>†</sup>

### State and Industry in France, 1750–1914

By CAGLAR KEYDER\*

For most students of the subject, French economic history is, as Shepard Clough called it, the “history of national economics” (1939). Especially in the Anglo-Saxon tradition, it is the otherness, or the contraposition to the presumed normalcy of the English case which draws attention to the history of the French economy. It is, of course, not accidental that the Anglo-Saxon tradition has upheld the British experience as the ratio since the successive hegemonic powers (Britain and the United States) defended, at least in their ideological posture, what is supposed to constitute the sufficient institutional basis of successful industrialization, viz, the autonomous market.

The French experience, on the other hand, despite its providing a model with a much more justifiable claim to universality, has been treated mainly in its distinction from the market paradigm of the first industrial country. Presumably it was the reversal in economic supremacy which became all too obvious in the 1970's that prompted revisionist work reassessing French industrialization. The principal contributions are by Richard Roehl (1976), and Patrick O'Brien and myself (1978). For reviews, see Rondo Cameron and Charles Freedman (1983), and N.F.R. Crafts (1984). There is, as yet, no attempt on the part of economists to draw the conclusion from this revisionism to advocate industrial policy and a state-economy relationship derived from the French experience.

What is of concern is the role of the state in the economy, or euphemistically, the nature of economic policy. At some essential level, France is the privileged locale where the state is visible and, to varying degrees, autonomous. This is not only a retrospective judgement: it was a constant theme in contemporary discussions as well, which aimed at discovering the best role for the state in constructing the desired national economy. At this level, fluctuations in French economic policy may be presented as various expressions of the essential nature of the state and its relation to the economy. From Nef through Boissonade, Cole, Heckscher, and Clough, the theme that runs through the accounts is *étatisme* whether in mercantilist, Colbertist, or interventionist and protectionist garb. There are certainly excesses and departures from the general line, but the continuity of the importance of the state is what sets France apart.

#### I

There are three not entirely independent explanations for the persistent importance of the state in French economy. The first focuses on the role and demands of the economically dominant classes—merchants, shippers, and industrialists. Confronted with British superiority, these groups appealed to the state for protection and the state responded with economic policy designed to secure the internal market and gain a better share in the world market for its prime constituency. In other words, French specificity results from the British economic threat and the domination of the French bourgeoisie over, or their collusion with, the political authority.

The evidence of a secular French inferiority in industry is far from conclusive, except in sectors which constituted the mainstay of

<sup>†</sup>*Discussants:* W. James Adams, University of Michigan; John Zysman, University of California-Berkeley.

\*Department of Sociology, State University of New York, Binghamton, NY 13901.

the industrial revolution, but French industrialists' unreasonable fear of British competition is well documented. On the other hand, it was not only industrialists who appealed to the state for protection against British competition, but also various colors of social reformers who were concerned that France should not repeat the British example of a socially disruptive, costly, and morally repugnant industrialization. In both cases, British presence was utilized to remind the political authority of its duties toward society and the economy. The main problem with this explanation is its instrumentalization of the state in the hands of the economically dominant groups. Cases such as the 1786 and 1860 treaties raise a difficulty with this view concerning the explanation of policy acts which ostensibly opposed bourgeois interests. This problem may be solved, however (though, I fear, unsatisfactorily), through a better understanding of the fractions within the bourgeoisie and their relative economic standing. The argument would then become that, with the exception of a few instances, dominant factions in economically dominant classes favored an extensive presence of the state in the economy, primarily for the sake of strengthening against and protecting from British industry.

The second perspective which seeks to define an essential pattern of the state-economy relationship extends the tutelage of the bourgeoisie under the political authority to a permanent dimension of the French social formation. In this view, it is the genetic strength of the French state, as it was constituted during the crisis of feudalism, and as it later perpetuated itself, which determines its relations to the economy.

The relative weakness of the landlords and the concomitant strength of the late feudal monarchy made for the consolidation of peasant property, ratified in the Revolution. By contrast, absolutist centralization failed in England where the aristocracy expropriated the peasantry and dominated the state. The syncretic relationship between the peasantry and the state allowed for the French monarchy and the bureaucracy first to withstand enclosure tendencies by the aristocracy and later, as exemplified in the Sec-

ond Empire, to establish an extensive state machinery relatively autonomous from the bourgeoisie. The central authority implemented its external and internal goals, such as military strength and domestic stability, necessarily through the manipulation of the economy. In other words, it has been a permanent feature of the French state to construct and guide an economy in its design. Bertrand Badie and Pierre Birnbaum (1983) provide the most explicit version of this "autonomy of the state" approach.

An objection to such an autonomization of the state would be expected from the orthodoxy seeing in the state a reflection of changing social balances, and more specifically from the proponents of the classical interpretation of the Revolution: for, if the bourgeoisie did not capture the state, then what exactly did the Revolution accomplish? If the state-economy relationship is unchanging, is there then no substantive difference between the bourgeoisie's relationship to state power in the eighteenth and nineteenth centuries? As is well known there is an active current, ranging from Furet to Wajda, attempting to de-construct the Revolution, and an argument for the constancy of the nature of the state would necessarily be revisionist in a similar vein. For a review of this literature, see Jack Goldstone (1984).

This revisionism aims at debunking what Furet called the "revolutionary catechism," but in doing so it tends to ignore the dimension of eighteenth-century reality whose transformation permitted the postrevolutionary state to engage in a qualitatively different economic policy. The eighteenth century had witnessed a dislocation of the privileged relation between the peasantry and the state to allow for tax-farmers and rentiers to indirectly exploit the peasantry. The state had been reduced to a role of intermediation between producers and a money bourgeoisie, organized at a central level. On the eve of the Revolution, three-fifths of the state budget served to pay the interest on public debt, thus curtailing the political authority's ability to implement any substantive transformatory policy at the level of the economy. This problem, which became manifest at the level of state finances through a fiscal crisis, is

widely considered to be one of the proximate causes of the Revolution, but it is not stressed that the Revolution dealt a decisive blow to this class of rentiers through the inflation of the *assignats*. Thus, in addition to laying out the institutional structure and the juridical forms of capitalism, the Revolution permitted the state to engage in economic policy to cultivate the bourgeoisie. This perspective suggests that the eighteenth-century state was heavily mortgaged to a stratum which could not be construed as the subject of an economic policy oriented to the construction of a national economy, and with the repudiation of the *assignats* in 1797, the state was freed of this indenture to return to its Colbertist nature. In other words, the Revolution may be interpreted as restoring the state to its essential status in the society.

Colbert has been frequently invoked as having "established a strong and virtually indestructible tradition in French economic policy which the bourgeoisie was to use and interpret in its own interests" (Tom Kemp, 1971, p. 34). In the sense of a tradition lending legitimacy to various measures of industrial policy, Colbertism was as good a rallying cry as any; however, it took upon a social dimension as well.

During the nineteenth century, the argument was frequently advanced by protectionists that industrial policy was the principal guarantor of stable employment and what they considered high wages in the manufacturing sector. A drift from the relative insularity of industry would necessitate rapid change leading to unemployment and lower wages and threaten the social compact. This might seem to be a strange argument since revolutions occurred nonetheless and since average wages were already appreciably lower than their British counterparts. (All the quantitative comparisons with Britain derive from the book by O'Brien and myself.) Yet, there might be some justification to the claim from the perspective of rural-urban income differentials. With a low demographic growth and a secure property regime based on peasant ownership, the push factor does not operate intensely, thus average incomes in agriculture plus the risk involved in abandoning them, have to be matched in the city for there to be any migration. Protection and

industrial subsidies probably allowed for maintaining higher wages than would have been the case under free trade. More importantly, however, protection permitted the survival of an industrial structure based to a larger degree than Britain on artisanal and small producing units. This combination of Colbertian tradition and a coalition formed by a variety of interests including the grande bourgeoisie, small capital, artisans, and workers induced the state toward conservatism when it came to the policy of protection. (See, for example, the essay by Claude Fohlen, 1956.)

Liberalization was widely considered an English plot locally supported only by Girondin merchants. By preventing social and economic dislocation, the state defended the status quo, and consequently industrial policy was characterized by a remarkable continuity of purpose. According to this third explanation, it was the historical formation of the society as a whole which induced its collective expression—the state—to protect it from disruptive forces. Since such forces were widely recognized as economic and external, the state had to take upon a prominent policymaking role in its relationship to the society. If the first explanatory attempt was orthodox and class reductionist, the second may be labelled politician and state-autonomist. The last one, by contrast, is pluralist as it appeals to the conjunction of all social interests.

## II

A second type of approach eschews characterization of the permanent nature of the state-economy relationship and instead engages in identifying successive periods punctuated by political events. The politicized character of the French state, especially in the nineteenth century, is reminiscent of Third World experience in the twentieth. Régimes were temporary; political institutions did not enjoy effective legitimation; and the system was questioned at every crisis. Policy change correlated with regime change.

The Revolution was the first fundamental break; soon followed the inception of the continental system and Waterloo, then the

coup d'état of 1830, the 1848 Revolution, the 18th Brumaire of Louis Bonaparte, the Commune and the German War, and the Third Republic. For each of the periods in between, competing interpretations of the state-economy relation are available and they usually refer to the government being more or less responsive to the bourgeoisie, or to particular bourgeois factions as opposed to others.

The periodization actually begins with the ancient regime; the state in the period after 1750 came under Physiocratic influence and was more recognizant of manufacturers' needs and, despite the adherence to the old instruments, "the intendants tended to become more concerned with encouraging entrepreneurs than with enforcing regulations" (Kemp, p. 72). Kemp's judgment may be opposed by this conclusion of Pierre Deyon and Philippe Guignet: "There is no reason for believing that manufacturing policy was radically transformed between the first and second halves of the century" (1980, p. 629).

The 1786 trade treaty with England was definitely an instance of liberalization although its application period was very short. Even if it was not the immediate cause of the pre-Revolutionary crisis, this treaty provided the Republicans with an ideological banner. The bourgeoisie wanted not only the constitution of a liberal economy based on national integration and private property, but also protection against foreign industrial and commercial competition. What was demanded in the *Cahiers* was rapidly fulfilled in the unfolding of the Revolution. First, of course, came the sanctity of private property among other juridical constellations and measures toward the economic integration of the country.

In 1792, the war and the defeat of the Girondin faction allowed the Convention to abrogate the Eden treaty and, shortly thereafter, to announce the start of economic warfare against England, which prohibited all British goods from entering French soil. The true promotion of the manufacturing bourgeoisie came through the economy of war-time mobilization and the Blockade. In the attempt to construct an autarkic Continental System, many industries which would have been doomed to failure under any

world-economic sanctioning prospered and must have allowed their entrepreneurs opportunities of rapid accumulation. The military end to the Continental System coincided with its internal dissolution through shortages, smuggling, and trade licenses granted by the government: the bourgeoisie had begun to find Napoleon's political direction of the economy dysfunctional. (On this subject, Eli Heckscher's 1922 book remains a valuable summary.)

Economic policy under the Restoration may be seen as a return to less radical protectionism, without the supplanting of the market that the Napoleonic system had resorted to. The new tariffs reflected the composition of the Chamber, where returning landowners and the bourgeoisie sat; once again the exporting interests of Bordeaux had been excluded from the coalition. They remained so under the July monarchy as well, which has been called the period in France when the state was the least autonomous from the grande bourgeoisie (Jean Lhomme, 1960, p. 57).

The grande bourgeoisie was a newly ascending class yet it successfully opposed the Bourbons who represented to a public, which now remembered only the glory of Bonaparte, the defeated Ancien Régime. Under Louis Philippe, bankers held actual power: as Marx described it, the July monarchy was a business concern for the finance aristocracy. They plundered the state budget through floating loans and railroad schemes; they prevented financial reform and rational bourgeois calculation. Nevertheless, the bankers succeeded in increasing credit and there was considerable industrial expansion even if not at revolutionary pace. The success of the financiers swelled the ranks of the bourgeoisie excluded from governmental posts and the numbers of industrial workers who joined forces in the 1848 revolution to overthrow the monarchy. The Second Republic accordingly aimed at neutralizing the power of finance by strengthening the Bank of France.

The subsequent phase could have been more directly dominated by the industrial bourgeoisie as the revolution seemed finally to have run through its arduous course: an attempt by Napoleon to build an economy

under political auspices, a short-lived restoration, a usurpation by the grand bourgeoisie of the liberal precepts punctuated by 1848. The factor of Bonapartism intervened.

The regime of Louis Bonaparte is a favorite of social scientists where a name provided an otherwise paltry character with charisma and the "normal" political representation of the economically dominant classes was interrupted. Relying on a mass constituency of peasants, workers, and the lumpen of Paris, and ruling by plebiscite, the authoritarian Bonapartist state could afford to be autonomous of bourgeois interests; the bureaucracy and the state machinery which had been centralized and rationalized under the uncle, attained their own power under the nephew.<sup>1</sup>

For Karl Marx, Bonapartism represented another effect of the overwhelming weight of the small peasantry as it determined the state-society equation (1963, pp. 128-31). By responding to the ideological aspirations of the small peasantry, Louis Napoleon could break the political power of the bourgeoisie. Under him, the administrative machinery increased in size, the bureaucracy became powerful, institutionalized and differentiated, and evolved into a self-sustaining cadre with its own schools and recruitment practice. The autonomization of the bureaucracy allowed for policies which were distinguished by their bolder approach to economic modernization. No longer ridden with conservative solidaristic fears of an industrial future, the government engaged in long-term financial policy, supported railway construction and rebuilt Paris under the guiding influence of Saint-Simonian bankers. Lifting official restrictions on the formation of joint-stock companies, an impetus was given to industrial investment and the transformation of industrial structure toward concentration. All such measures may be interpreted within the framework of a state structurally bound to capitalism, but enjoying an instrumental

autonomy from particular groups within the bourgeoisie.

In light of what seemed to be a unanimous opposition to trade liberalization, the 1860 Cobden-Chevalier treaty with the principal economic rival across the Channel and subsequent treaties with other European countries is the most surprising act in the Bonapartist repertoire. This was truly a revolution from above where, according to one interpretation, Napoleon was convinced that he could appraise long-term interests of the bourgeoisie, and despite complaints in the short run, the bourgeoisie, with the exception of a few intransigent protectionists, were grateful. (Marcel Rist, 1956, and Lhomme both endorse this interpretation.) Yet by the end of the 1860's, the general will had begun to crumble and the Third Republic witnessed a return to many of the older constants of economic policy.

The relative political stability of France until World War I represents a new equilibrium between the state and the economy. During this period, neither the bourgeoisie nor the bureaucracy were unilaterally capable of formulating policy. Nationalist sentiment after the German war had created a consensus behind a gradual departure from free trade, and especially following the crisis ushered in by the 1873 financial collapse, agricultural and industrial interests could meet on a common ground albeit under the latter's domination. Soon, however, the agricultural depression and its more general consequences in the economy created sufficient pressure in the direction of conserving France's agrarian structure. The peasantry was once again saved through the Méline tariff, and once again, as Eugene Golob says, "the fate that had befallen English agriculture" (1944, p. 9) was avoided. A sturdy peasantry would ensure that industry and agriculture could enjoy a balanced growth, in conformity with the national economic teaching of the day.

The economic boom that followed the 1892 tariff seemed to confirm protectionist hopes, but it also brought with it an increased willingness by various groups within the bourgeoisie to entrench their particular interests into state policy. The parliamentary system,

<sup>1</sup>The concept of the Bonapartist state derives from Marx's work (1963); Nicos Poulantzas (1973) gave it new currency in the late 1960s. For a review of the literature in France, see Alain Rouquié (1975).

by now stabilized, provided the political structure for such contestation and closure. As the French economy lost its relative share in world trade, partly due to the tariff, the boom built on her peculiar social structure continued and it was precisely in the two decades preceding World War I that total commodity output increased to exceed Britain's. Industrial output as a proportion of Britain's had declined from 1.3 around 1860 to 0.65 by late 1890's; the 1905-14 average increased to 0.7.

### III

I have, thus far, examined the state-economy relationship as manifested in sharp breaks in general policymaking. There is, however, another realm where the shifts are not so visible, but the political input into the economy is at least as important—that of state expenditures. From the above discussion it would be expected that the periodization based on regime changes with alternating perspectives on economic policy would also be a good predictor of state expenditures, where, for instance, increasing fiscal presence correlated with attempts at building the national economy. It appears, however, that state expenditures vary according to a different periodicity, one taking shape largely outside the French economy.

Louis Fontvieille (1976), in his construction of statistics on state expenditures in the ISEA series which include Toutain's estimates on agriculture, Markovitch's on industry and Marczewski's on physical output, finds that state expenditures as a proportion of physical product, show a secular tendency to increase, from around 10 percent until 1870 to around 15 percent before World War I. More importantly, however, the share in state expenditures of what might be called social investment, or what Fontvieille terms "expenditures related to the development of the national economy" increase from 3-4 percent in the first half of the century to 7-8 percent. This evolution is as expected; what is surprising in the fluctuations around the long-term trend is the author's finding that Kondratieff cycles are correlated with the stagnation or the spurts in the ratio. Thus,

during *A* phases of economic prosperity (1848-73 and 1896-1914) the ratio is stable or even declines, while in *B* phases of depression (1815-48 and 1873-96), it increases rapidly.<sup>2</sup> In other words, successive governments, regardless of the character of the regime, seem to have practiced countercyclical policy, in particular an injection of state expenditure into the industrial social capital. For Fontvieille, this finding allows the conclusion that the development of the state apparatus is determined by the devaluation and accumulation needs of capital in the successive stages of development of industry.

This explanation of the movement of state expenditure has been challenged and debated especially on grounds that the fluctuations in French economy do not exactly correspond to standard Kondratieff cycles. Although it does not constitute sufficient proof of the state being an instrument of the bourgeoisie, the correlation Fontvieille has discovered remains strong. In one case, that of the Plan Freycinet, a public works program which was initiated in 1878, the intention of counteracting the crisis of industry, especially in the iron and steel sector, was clear.<sup>3</sup> Although the Plan Freycinet's extraordinary budgets ended in 1882 and financial orthodoxy reasserted itself, state expenditures as a proportion of physical output continued to grow until the end of the Great Depression.

### IV

Long-term structural concerns emphasizing permanence and attempts at accounting

<sup>2</sup>"Related expenditures" consist of public works, social and economic activities, education, colonial expenditures and interest payments on the public debt. According to Fontvieille, the ratio of related expenditures to physical output increased from 2.4 to 4.4 percent between 1815 and 1849; from 5.4 to 8.9 percent between 1870 and 1895; while between 1850 and 1869, it only moved from 3.9 to 4.1 percent, and from 1895 to 1913, it actually declined from 8.9 to 7.1 percent (p. 1673).

<sup>3</sup>Yasuo Gonjo's article (1972) on the Plan Freycinet makes its industrial market creation dimension very clear.

for observed fluctuations through a periodization need not be alternatives. They bear the same complementary relation to each other as analyses of *longue durée* and *conjecture*. There was, in fact, a distinctive social structure in France during the development of its capitalism. This structure determined a certain institutionalization and autonomy of the French state which shaped its absolute presence and the instruments it possessed in intervening in the economy. And this state form evolved, after Colbert, in a direction which established the bureaucracy's relative strength and ability to implement their visions of the national economy. Regimes, on the other hand, changed rather rapidly, without, however, altering the basic state-economy relationship. They did allow more or less representation to the bourgeoisie, arguably in relation to world and national economic conjuncture; and it seems that regime changes sometimes led to a ready assumption of policy change.

Specific policies may not be seen as simply deriving from either the essential nature of the state or the character of the regime: it was the interaction between the momentum of the state originating indeed in the absolutist consolidation (Colbertian étatism and its mercantilist assumptions of rivalry) and the conjunctural needs of industrial capitalism (as these were reflected in political regimes) which shaped them.

# French Industrial Policy under the Socialist Government

By BELA BALASSA\*

In presenting the draft law on nationalizations in French industry and banking to the National Assembly on September 27, 1981, "the lack of a true industrial policy" was adduced as the principal reason for the proposed actions. It was claimed, in particular, that "it is necessary for the state to have the instruments for efficient interventions and for the planned orientation of the country's development. The most important of these instruments is the enlargement of the public sector." The enlarged public sector was to be the "fer de lance" of modernization of the French economy, with the state providing the funds for the requisite investments. Modernization appeared as the key word in statements made by socialist leaders, who repeatedly claimed that "there are no condemned sectors, only outdated technologies."

The objective of developing simultaneously all sectors while improving technology was reiterated in a speech before the chief executives of public enterprises in the industrial sector on August 31, 1982, by Jean-Pierre Chevènement, then Minister of Research and Industry. A year later his successor, Laurent Fabius, now Prime Minister, suggested in a speech made to the National Assembly on October 31, 1983, that "an industrial strategy involves the choice of the principal national priorities...in pursuing two major objectifs: to contribute to the re-establishment of economic equilibria in particular in employment, and to modernize the industrial structure."

This paper will review the French record with industrial policy since May 1981. It will

examine the experience of the major industrial sectors, discuss the actions taken, evaluate the results of these actions, and indicate possible future prospects.

## I. The Experience of the Major Industrial Sectors

Coal, steel, and shipbuilding, three declining industries, exhibit a similar pattern. After May 1981, a reversal occurred in the process of restructuration that would have entailed continued reductions in output and employment. The targets were raised substantially above actual production levels, leading to new hiring. With declining demand and the rise of wages and social changes, including a fifth week of vacation and full compensation paid for the reduction of the work week from 40 to 39 hours, there resulted a considerable increase in the deficits of the firms in the three industries.

Notwithstanding the rise in budgetary appropriations, the firms in question had to increase their borrowing, thereby raising levels of indebtedness. By 1984, long-term debt surpassed the value of output in the coal mining industry, it was one-half of output value in steel making, and in between these two figures in shipbuilding. In the same year, deficit and budgetary support combined amounted to 140 thousand francs per worker in coal, 115 thousand francs per worker in steel, and 175–200 thousand francs per worker in shipbuilding. By comparison, the average wage in the manufacturing sector was 110 thousand francs.

High financial charges on their debt will continue to add to the losses of the firms in the three industries. Further costs are involved in connection with the so-called congés de conversion, under which the workers who are considered superfluous are receiving over a two-year period, 70 percent of their pre-tax salary, financed one-third each by the firms themselves, from the government budget, and by the unemploy-

\*Professor of Political Economy, Johns Hopkins University, Baltimore, MD 21218, and Consultant to the World Bank. I am indebted to French economists, businessmen, and government officials for helpful discussions on the subject matter. I alone am responsible, however, for the opinions expressed herein; they should not be interpreted to reflect the views of the World Bank.

ment fund. Also, in some cases, substantial bonuses are offered to workers who depart voluntarily (50,000 francs in one of the large shipyards).

The automobile industry was traditionally an important export sector in France. The position of the industry deteriorated to a considerable extent in external as well as internal markets after May 1981, however. Thus, its share in European markets fell from 30.4 percent in 1980 to 24.3 percent in 1983, whereas the share of foreign cars in France rose from 21.7 to 32.7 percent. During the same period, the combined losses of the Peugeot and Renault groups increased from 1.2 milliard to 4.3 milliard francs.

Several factors contributed to these results. According to estimates cited in the report of the Conseil Économique et Social, the measures taken after May 1981 increased labor costs in the automobile industry by 19.5 percent in 1982. At the same time, the price control introduced in June 1982 did not allow for offsetting increases in prices, giving rise to foregone revenue of about 2.5 percent. Finally, social troubles, fostered largely by the C.G.T., involving strikes, production slowdowns, and the deterioration of product quality, contributed to declines in market shares and added to losses, which were increased further as the labor unions obstructed reductions in the industry's work force.

The losses incurred have in turn given rise to high financial charges, accounting for about 4 percent of total costs in the two groups. At the same time, their long-term debt came to exceed two-fifths of the total value of sales, with the ratio of the debt to capital approaching 2, compared to ratios between 0.2 and 0.9 for major competitors abroad.

The deterioration of the financial position of the automobile companies has not permitted undertaking the necessary investments in automation that have been carried out by foreign competitors. The difficulties encountered in reducing employment have also discouraged automation and labor productivity practically stagnated between 1980 and 1983 in the French industry, compared with gains of about 20 percent in General

Motors, Ford, and Fiat. These results, cited in a report, prepared in the summer of 1984 by a commission chaired by Francois Dalle, the president of the L'Oréal cosmetics group, reflect excessive manning levels in French automobile factories. According to the same report, the work force of 230 thousand in the industry in June 1984 should be reduced to 160 thousand by 1988.

Among high-technology industries, France made considerable progress in nuclear energy and in aerospace during the 1970's. Its record in electronics was mixed, with strengths in telecommunications and in professional electronic equipment, and weaknesses in electronic components, such as integrated circuits, in computers, and in electronic consumer goods. On coming to power, the socialist government gave considerable emphasis to electronics, with a view in particular to strengthen the weak areas. It further set out to develop fiber optics for use in a nationwide network of cable transmission.

The plan "filière électronique" envisaged spending 140 billion francs (in 1982 prices) on investment and R&D in electronics over a five-year period. Within this total, 11-12 billion francs a year were to have come from the government budget. In fact, 9.5 billion francs were spent in 1983 and an estimated 11 billion francs in 1984, but in current rather than in constant prices. Although comparable data are not available, it appears that the shortfall has been even greater as far as expenditures from nongovernmental sources are concerned.

The spending actually undertaken nevertheless represents an increase over the 1970's, permitting the French electronics industry to reach a rate of growth of output of 8 percent in 1983. However, in the same year, the rate of expansion of output was 16 percent in Japan. Furthermore, several questions arise in regard to the future prospects of the French electronics industry.

To begin with, one may query the desirability to "faire cavalier seul" in integrated circuits and computers. A similar effort failed earlier in the so-called Plan Calcul. In both industries, technological change is very rapid and alliances with foreign firms provide advantages for the development of new tech-

nology; European firms outside France have in fact entered into such alliances with American and Japanese firms.

Further questions arise concerning the planned expansion of the production of electronic consumer goods in France. Alongside the failures, such as the Plan Calcul and Concorde, French industrial planners were successful in the past in developing branches of electronics where both supply and demand were dominated by the state, thereby imparting considerable stability to the market.

In the case of consumer electronics, however, tastes change rapidly and centrally made plans easily go awry. Also, government interventions in production decisions, such as compelling Thompson to build a factory producing parts for video recorders in Longwy, interfere with firm decision making and increase costs. And, while in France the restructuring of the nationalized firms has led to the establishment of monopoly positions, the American experience indicates that small firms have the advantage of flexibility in catering to consumer needs and competition becomes a force of progress.

France has also chosen a highly centralized alternative for establishing a nationwide cable network, to be controlled and financed by the Direction Générale des Télécommunications of the PTT. By contrast, in Britain, there will be competing cable networks to be financed privately, as in the United States.

With the deterioration of the financial position of the PTT and the policy of austerity, only about 2 billion francs of the total of 60 billion have been spent so far on experimental schemes in a few cities in France, and considerable delays have been experienced compared to the original plan. At the same time, the installation of the fourth TV channel (Canal-Plus) on a subscription basis may have preempted the role of cable to show feature films, and plans have been formulated for a joint French-German satellite venture, thereby raising questions about prospective demand for cable on the part of individual households who are all supposed to be linked into the nationwide network. Finally, notwithstanding the technological capabilities of optical fiber, chosen by the

French government over coaxial cable, it is not evident that a cable network will have economic advantages over other alternatives, such as a combination of satellite and terrestrial microwaves that has been used in the United States.

## II. Government Support to Industry: *R&D and Industrial Finance*

Soon after the socialist government came to power, spending on research and development was targeted to grow 20 percent a year between 1981 and 1985, and to increase from 2.0 to 2.5 percent of the gross domestic product (*GDP*) during this period. In the event, the share of *R&D* spending in *GDP* is estimated to have reached 2.2 percent of *GDP* as budgetary appropriations for research have been cut back in the period of austerity. The cutbacks affected primarily the financing of research programs that promote industrial research and provide equipment for laboratories. In turn, funds for the construction of the giant museum of science and technology at La Villette were not reduced.

France has traditionally practiced a policy of selective credit. This policy has been extended further after May 1981 through the establishment of CODEVI (*compte de développement industriel*) that provides advantages to savers over alternative instruments; the creation of FIM (*Fonds Industriel de Modernisation*) that receives an important part of CODEVI's resources for distribution to industrial firms and also borrows in domestic and in international markets; and the introduction of special institutional arrangements in favor of small- and medium-size enterprises.

The new institutions perform some of the functions customarily assigned to banks, in the present case the nationalized banks. Their operation has involved increased public interventions as loans by FIM are subject to approval by the ministry for foreign trade and industry, and other credit arrangements depend on decisions by local authorities. Furthermore, with the state guaranteeing loans by FIM in full, unprofitable operations may also receive financing. More generally, increasing the scope of selective credits tends

to reduce the efficiency of the allocation of financial resources while adding to the complexity of the credit system.

A further question is if the new institutions have actually increased the amount of funds available to industry. While data availabilities do not permit one to gauge the amount of credits accorded to the individual sectors, all enterprises taken together have seen their share in total credit decline as public deficits have increased. Thus, as Renaud de la Geniere, the Governor of the Banque de France until November 1984, noted in a presentation made at the Académie des Sciences Morales et Politiques on January 26, 1984, the net credit requirements of the public authorities that were practically nil in 1979 but reached 115 billion francs in 1983, compared with 160 billion francs for the enterprises whose net borrowings were 105 billion francs four years earlier. During the same period, the capacity of financing by households and financial institutions increased only from 105 to 200 billion francs, thereby necessitating borrowing abroad.

If the lack of credit is not an obstacle to investment (according to the latest survey by INSEE only 9 percent of industrial enterprises regarded credit to be a constraint), this seems less to do with the existence of new financial institutions as with factors such as insufficient profit margins (48 percent of responses) and the desire to avoid further increases in indebtedness (37 percent), which rose to a considerable extent in 1981 and 1982 when profit margins were particularly low. And while profit margins improved in 1983, the decline in industrial investment was not reversed.

With further improvements in profit margins, increases in industrial investment in 1984 and in 1985 may permit regaining the level reached in 1980, although public investment in steel accounts for a substantial part of the total. At the same time, the fall in industrial employment would continue and may even accelerate. Thus, annual decreases of 3 percent are estimated for 1984 and 1985, compared with declines of 2 percent in 1982 and in 1983.

The expected fall in industrial employment reflects the labor-saving character of

investments in response to higher labor costs, increased social charges, and, in particular, the difficulties encountered in attempting to reduce the size of the labor force if and when economic conditions warrant. Thus, as the freedom of enterprises to dismiss workers has been increasingly constrained, there has been a growing reluctance to hire labor, notwithstanding the measures taken in favor of the establishment of new enterprises in general, and small- and medium-size firms in particular. By contrast, greater flexibility in labor remuneration as well as in firings has contributed to the rapid expansion of employment in the United States.

### III. Concluding Remarks

In line with its expansionary stance, after May 1981 the socialist government postponed the necessary adjustment in French industries while wages and social charges increased to a considerable extent. And, once the need for adjustment came to be understood, the government wished to avoid firing superfluous workers in the nationalized firms. The financial situation of these firms was further aggravated by the interest costs of borrowing to finance their deficit over and above their increased budgetary allocation.

Thus, while budgetary allocations to the newly nationalized firms doubled (from 21.8 billion francs in 1980 to 43.4 billion francs in 1983), their deficit was nearly five times higher in 1983 (11.4 billion francs) than in 1980 (2.4 billion francs). During the same period, a surplus of 1.5 billion francs turned into a deficit of a similar magnitude, rising further to an estimated 9.0 billion francs in 1984 at Renault that has suffered the consequences of higher wages and social charges, price control, and social troubles fomented largely by the C.G.T.

At the same time, providing for the increased financial needs of the declining sectors has limited the availability of funds for the expansion of high-technology activities. Also, higher wages and social charges and price control discouraged investment activity in the years 1981–83. Correspondingly, new activities did not expand sufficiently to take the place of the old ones and industrial em-

ployment declined. A continuation of this trend is expected, notwithstanding a rise in industrial investments that tend to be labor saving.

In these circumstances, the question arises if one can speak about an industrial policy in France. As an official of the French government suggested in private conversation, the measures applied in regard to the three declining sectors may be considered social policy rather than industrial policy. Nor can we speak of an industrial policy in regard to the automobile industry, where the state has repeatedly countenanced actions taken by the unions. And while the policies applied aim at encouraging the development of the electronics industry, questions arise about the efficacy of the measures applied.

But how about the role of the nationalized firms as instruments of industry policy? After detailed interventions under Chevènement's tenure as minister failed to bring the expected results, Fabius reduced the extent of interventions while the policies applied by Cresson are not yet clear.

At the same time, the procedures of appointment of the managers of the nationalized enterprises give rise to concern. Adding union representatives to the board of directors has led to the adoption of an accommodating stance towards union demands on the part of management, in particular at Renault. Also, the contracts of two chief executives who showed considerable independence, Raymond Lévy of Usinor and Daniel Deguen of the Crédit Commercial de France, were not renewed. At the same time, there are signs that political considerations increasingly enter into the choice of chief executives.

In any case, the appointment of a chief executive for two years does not provide a sufficiently long learning period and favors the adoption of a short-term horizon. In fact, indications are that the chief executives of nationalized companies in France increasingly tend to take a short-term view, with the

neglect of long-term considerations, so as to increase their chances for reappointment.

Under the present ownership structure, these shortcomings may be mitigated by lengthening the terms of appointment of the chief executives and changing the composition of the board of directors, so as to minimize the chances of political interference. In this connection, reference may be made to attempts in Hungary for increasing the independence of the managers of state enterprises.

As to industrial policy, increased emphasis would need to be given to horizontal measures that operate across-the-board as against vertical measures that pertain to individual industries. In particular, there would be need to eliminate price control and to reverse increases in social charges. It would further be desirable to ease the constraints imposed on small- and medium-size enterprises in the form of additional social charges and workers' participation. Finally, greater flexibility would need to be introduced in labor markets.

The described measures may be expected to contribute to increased industrial investment and employment without the need for vertical interventions that tend to lead to inefficiencies in resource allocation. Horizontal measures would also need to be given emphasis in the support of research and development in the form of tax benefits for the *R&D* activities of the firms that generate external economies.

At the same time, the health of French industry, and of the French economy in general, is contingent on the pursuit of appropriate macroeconomic policies. Due to the weakness of investment activity and continued borrowing abroad, the rising budget deficit has not created a credit crunch for enterprises so far. But, with the constraints on foreign borrowing, the sustained rise of investment by enterprises would require that the public authorities limit their encroachment on domestic financial markets.

# *ECONOMIC HISTORY: A NECESSARY THOUGH NOT SUFFICIENT CONDITION FOR AN ECONOMIST<sup>†</sup>*

## Maine and Texas

By KENNETH J. ARROW\*

Henry David Thoreau said about the newly invented telegraph: "They tell us that Maine can now communicate with Texas. But does Maine have anything to say to Texas?" I suppose the existence and location of this panel shows that California and Massachusetts, at least, have much to say to Texas. But, as Dante explained so long ago, we must interpret texts not merely literally, but also allegorically and even spiritually. Our assigned subject asks that Maine and Texas be interpreted as Economic Analysis and Economic History, though not necessarily respectively.

I use the term "analysis," rather than "theory," because I want to contrast the aims of history and those of social science. Permit me to use the changes in my own thinking as illustration. I always found history very interesting and read heavily. As a graduate student, I qualified in economic history, which was compulsory, and never felt it to be an intrusion, as later generations of students did. As a faculty member, I had to consider the role of economic history in the curriculum, as well as the problem of filling vacancies there. I took it for granted that history was a necessity but recognized the difficulty of finding scholars who were both economists and historians. This was in the early 1950's, before a new generation solved that supply problem. I took it for granted that the role of history in the educa-

tion of economists was as empirical evidence. It was a way of testing theories, on a par with contemporary empirical evidence. This view was reinforced by what was then the most significant use of history in economics, Simon Kuznets's development of long time-series on national income and its components, with its strong implications for economic development and for the consumption function:

A lecture by the historian, Leonard Krieger, changed my view of the nature of history. There was then much discussion of the role of social science in history in general. Krieger was regarded as among the historians most sympathetic to social science. But in his lecture he made clear that history could not be regarded as simply a branch of social science. Its aims were different. It sought to study the individual case, while social science aimed at general principles. Social science, whether economics or another, might indeed be useful and even vital in interpreting a past event. Certainly, psychological theories of different kinds have been used, possibly not always with the best results, in interpreting the behavior of political leaders. But the use was to illuminate the particular event. The aim of historical study as such was not simply to serve as a source of data from which to infer and to test social science generalizations.

Of course, this does not preclude the use of the data thrown up by historical investigation for the purposes of social-scientific analysis. The two modes of inquiry are complementary, not substitutes. But they are not identical.

Let me draw a very close analogy from the natural world, that of geology. The underlying laws of geology are nothing but the standard laws of physics and chemistry.

<sup>†</sup>*Discussants:* Albert Fishow, University of California-Berkeley; Donald N. McCloskey, University of Iowa; Gavin Wright, Stanford University.

\*Departments of Economics and Operations Research, Stanford University, Stanford, CA 94305.

There is, from the viewpoint of scientific generalizations, nothing peculiar to geology. That water wears down rocks, that heat sources in the interior of the Earth can produce great changes in the Earth's surface, that the energy of the Earth derives in major part but not entirely from solar radiation, that under temperature and pressure the materials of the Earth form new chemical combinations, these relations and others determine the entire course of the Earth's development. Further, examination of the history of the Earth could in principle yield evidence about the measurements of specific chemical and physical reactions. In practice, though, observation in the laboratory is so much more efficient that the evidence of geological observation has probably been of little use to the underlying sciences except by way of suggesting research problems.

But geology is in fact a flourishing subject, and much of its interest is in the specific historical event. What is the history of the Appalachians and the Himalayas? What have been the movements of the Indian subcontinent? Why does Hawaii have the shape it does? It is in good measure a study of the specific. It is indeed history and a fascinating one.

The example of geology illustrates a recurrent topic in economics. Is economics a subject like physics, true for all time, or are its laws historically conditioned? The importance of history was on the rise throughout the nineteenth century, just when the abstract economic theory of David Ricardo was developed. Ricardo's doctrines were much attacked by contemporaries for lack of historical understanding. His disciple, John Stuart Mill, made clear that the laws of distribution were indeed historically conditioned; the classical laws of value held only in an economy in which exchange was governed by markets. So, too, the theory of plate tectonics is historically conditioned. It is a valid statement about the Earth today and for a long period in the past. It could not have held when the Earth was sufficiently hot, and it may or may not be true of other planets.

Physics and chemistry have clearly been very useful to geology, interpreted as history.

What does standard economic theory have to contribute to economic history? It could fail on several grounds. It might be so overwhelmingly powerful a theory that history becomes uninteresting, merely a playing out of a well-defined script. It could be so wrong that it is an obstacle to understanding. W. J. Cunningham attacked Ricardo and Marshall about 1890 for interpreting rent in the Tudor period in Ricardian terms, not recognizing the differences in historical conditions.

The first obstacle, the power of the theory, is clearly not valid, though some economic theorists have spoken as if it were. In form, neoclassical theory is a statement of the implications of tastes, technology, and expectations for prices and quantities. (Other variations of economic theory have a similar form, though different content.) There is plenty of room for historical specificity in the conditions even if economic theory were more reliable than it is in drawing conclusions from them. There is nothing in economic theory which specifies that tastes remain unchanged, and a great deal of empirical knowledge about changes in technology. Indeed, it may be complained rather that economic theory does not sufficiently constrain historical determination, particularly when the data are not sufficient.

In fact, I think it would be widely accepted that using the ideas and approaches of economic theory has been useful in economic history. Perhaps most important, economic theory has raised new questions for history. It asks how economic institutions work in redirecting the flow of resources, not merely their intended workings. Our views of the relations between railroads and economic growth in the nineteenth century, of the diffusion of specific technological innovations such as the reaper, or of the economic consequences and functioning of slavery have all been seriously altered in ways that required new ways of thinking and suggested search for new kinds of evidence. Measuring the economic conditions of the masses of the population may have been driven by political aims as much as by modern welfare economics, but the appropriate measures and data have certainly been much clarified by the latter. I have already alluded to long time-

series on national income, a concept drawn from economic analysis, as a major contribution to our understanding of the past, both as to constancies and as to structural change.

But the example of national income analysis does remind us of a danger in the use of economic theory in economic history. There is a bias towards flattening out the particularities of the past. The more one uses categories drawn from the need to generalize, the less marked is the difference among the instantiations. This is not a logical consequence of the use of theoretical constructs. As already emphasized, each historical episode can in principle be interpreted as the application of general principles to unique contexts; but the bias drawn from theory is likely to be to emphasize generality at the expense of particularity. One is reminded of earlier modes of historical interpretation, in which every catastrophe was the workings of the hand of God. Consider also the many theories for the interpretation of myths, where they are all considered as illustrations of some general principle, whether it be Frazer's dying king, Muller's rising and setting sun, or Freud's Oedipus complex, or even the structuralist seeking of a universal form to myth. What is lost is the sense that myths are different; it is not true that when you've heard one, you've heard them all.

What about the uses of history in the development of economic analysis? There are many, but let me pick two, both alluded to earlier. One is simply the use of economic history as a source of empirical evidence for testing theories and estimating relations, what I referred to earlier as my naïve view on the role of history. It is far from exhausting the content of history, but it is certainly one of its uses. When an examination of long time-series shows that interest rates do not fully adjust for inflation, as Lawrence Summers has recently shown, the routine acceptance of the Fisher effect in analysis of contemporary conditions must surely be questioned. The regular patterns of consumption described by Engel's laws can be confirmed by historical shifts in industrial structure as well as by budget studies, incidentally making it hard to maintain simple models of homogeneous economic growth. Studies of past hy-

perinflations and their endings test theories of inflation. The historical analysis of individual business cycles was a live field after the pioneering work of Walt Rostow from 1946 to about 1960; it was neglected because of one-sided theories, first Keynesian and then monetarist, but I hope Peter Temin's work signals a revival. Such work is both history itself and a testing ground for the many relations which define cyclical fluctuations.

A second use of history in the development of economic analysis is a definition of its historical conditioning, to pick up again an earlier point. Before economic analysis had much of an effect on economic history, historians debated whether and which earlier periods could be described as capitalist or almost so. The great classical historian, M. I. Rostovtzeff, found the early Roman Empire to be governed by modern economic institutions, mobility, profit seeking, and so forth. He has been ridiculed for this by the current leading authority, Moses Finley, who finds little evidence of rational economic behavior in the ancient world. Again, Henri Pirenne found merchants and traders in a few centuries around the year 1000 to be thoroughgoing profit seekers, acutely sensitive to price differences; but the crystallization of the guild system, according to Pirenne, subsequently created a different economic world. It is not for the theorists to assess the very specialized evidence available. Still, there is some suggestion that the economic world of the past is not entirely different from that of our theories in the sharp rise in real wages after the radical shift in the land-labor ratio occasioned by the Black Death.

Closely intertwined with historical conditioning of theory is national or cultural conditioning. The study of the past is similar to that of the present elsewhere. There are, or at least seem to be, very large differences even among capitalist countries in such basic economic variables as savings rates and rates and levels of productivity growth. We find them even between such economically and culturally similar nations as the United States and Canada; there are significant differences in per capita incomes, productivity (even controlling for capital equipment, as in the

automobile industry), and labor union membership and activity. When we go farther afield, the differences increase. Studies have shown, for example, that real wage flexibility is distinctly lower in Western Europe than in the United States. Among the many differences between Japan and the United States, we might notice differences in industrial organization even in virtually identical technologies. Large corporations there perform innovative tasks which here seem best done by small firms. Perhaps connected are the well-known or at least widely alleged differences in organizational loyalty and the role of consensus in decision making within the large firm.

Cross-country comparisons of this kind are analogous to historical comparisons in exploring the range of validity of economic generalizations. But the relation is deeper.

Presumably, the international differences, insofar as they are not simply explainable by differences in natural resources, are themselves the result of history. It has frequently been suggested by political scientists that the fact that the United States was created by a revolution while English-speaking Canada was in part a reaction to the American Revolution has important and lasting effects. The cultural differences between nations, with all their implications for polity and economy, are precipitates of past events, sometimes from the far past. In an ideal theory, perhaps, the whole influence of the past would be summed up in observations on the present. But such a theory cannot be stated in any complex uncontrolled system, not even for the Earth, as we have seen. It will always be true that practical understanding of the present will require knowledge of the past.

## Is History Stranger than Theory? The Origin of Telephone Separations

By PETER TEMIN AND GEOFFREY PETERS\*

The integrated Bell Telephone System that we all grew up with vanished on January 1, 1984, to be replaced by a new, more open telephone network still in the process of definition. AT&T's divestiture of the telephone-operating companies resulted from the settlement of an antitrust suit against AT&T begun in 1974 and carried forward under three administrations. The trial was conducted in 1981, largely under the direction of William Baxter, the first Assistant Attorney General for Antitrust in the Reagan Administration, and the settlement was negotiated by him and the management of AT&T.

Baxter articulated his theory of the case to Senator Thurmond's Judiciary Committee midway through the AT&T trial. He said, among other things, "If one argues for divestiture, one argues that the cross-subsidy problem is terribly important, that the vertical integration economies probably are not very great, and that regulatory supervision is unwanted and more deregulation is possible" (1981, p. 27). Divestiture, in other words, would solve "the cross-subsidy problem" without doing much violence to the telephone network.

What is the cross-subsidy problem? As expressed by the government's economics experts in its antitrust suit shortly before Baxter's testimony, it was that AT&T's integrated structure gave it the opportunity and the incentive to subsidize its competitive long-distance services with revenues from its regulated local monopolies. (Bruce Owen, 1981; Nina Cornell, 1981) This, presumably, was one of the antitrust violations on which the government's suit was based. It is en-

tirely in accord with the lines of the negotiated divestiture. And as expressed by the government economics experts, it was a theoretical proposition.

Yet Baxter said to the Judiciary Committee, "Historically, AT&T has subsidized local telephone service with longlines revenues" (p. 27). And he continued that this pattern "probably" continued at the time of his appearance before the committee. Historical observation, in other words, opposed the theoretical proposition. Confusion on this scale—in which the Assistant Attorney General took one position while his expert witnesses took the opposite—cries for explanation. The explanation demonstrates the need for historical as well as theoretical analysis.

A little terminology will facilitate the historical narrative. A telephone "station" is what we colloquially refer to as a telephone. A toll "board" is the local exchange switch which routes local calls within the exchange and toll calls out of the exchange. There are two distinct models of telephone communication which have given rise to two different modes of accounting. In station-to-station accounting, a long-distance call is thought of as going from one telephone (station) to another. In the board-to-board model, the same call is broken into parts. The parts between the individual stations and their local exchanges (boards) are considered local; the long-distance call goes only between the local exchanges, that is, from board to board.

AT&T established its first toll rate schedule in 1889, the rates becoming applicable as service was opened. AT&T established its accounting on a board-to-board basis, reflecting both its initial conception of telephone communication as it developed from local service to a national network and its corporate organization (FCC, pp. 370–75).

The Postmaster General operated the telephone system during World War I. Not sub-

\*Massachusetts Institute of Technology, Cambridge, MA 02139, and New England School of Law, Boston, MA 02116. This research was supported by a grant from AT&T. All interpretations and conclusions are ours alone.

ject to the jurisdictional limitations that would later separate state and federal regulatory authorities, he set uniform interstate and intrastate toll rates which remained in effect through 1926, when AT&T instituted an interstate rate reduction. The FCC negotiated four additional reductions in interstate telephone rates before World War II, but did not attempt to separate interstate and intrastate assets during these rate negotiations.

The issue of accounting models arose in a case of intrastate rate determination. Illinois Bell had contested a rate reduction ordered by the Illinois Commerce Commission in 1923, and the case reached the U.S. Supreme Court as *Smith v. Illinois Bell*. The Supreme Court ruled that the issue of whether the mandated rates were "confiscatory" under the Fourteenth Amendment could not be decided without "specific findings" on the allocation of Illinois Bell's assets between interstate and intrastate service.

Referring to the "indisputable fact" that "exchange property" is used both for intrastate and interstate service, the Court said that, "It is obvious that, unless an apportionment is made, the intrastate service to which the exchange property is allocated will bear an undue burden—to what extent is a matter of controversy" (*Smith v. Illinois Bell*, p. 151). In other words, the "specific findings" needed to determine whether rates were confiscatory were to be based on station-to-station accounting; intrastate telephone rates had only to be set high enough to earn a satisfactory return on the capital under state jurisdiction.

The issue was considered by various states in the 1930's, but the FCC only began to examine the division of assets between interstate and intrastate activities during World War II when wartime traffic raised Long Lines' profits above the level allowed by the FCC. The FCC needed both to reduce Long Line's profits and to respond to the federal government's needs during World War II, which included strenuous demands on the interstate telephone network. And the Commission was acutely aware of the concerns of state regulators about the difference between interstate and intrastate rates for telephone calls over the same distance. As interstate

rates declined, comparable toll calls within states came to cost more than calls crossing state lines (NARUC and FCC, 1951).

The traditional way of reducing Long Line's "excessive" profits, reducing interstate rates, therefore was doubly problematical: it would increase the disparity between interstate and intrastate toll rates and also the quantity of interstate toll service demanded by the nonmilitary public. The FCC therefore sought to reduce Long Lines' profits by moving some expenses of local telephone service into interstate jurisdiction, that is, by using station-to-station accounting. Agreement on the use of separations procedures that divided expenses along station-to-station lines was reached in a series of meetings between representatives of AT&T and several FCC Commissioners in January, 1943. (See our forthcoming article which contains documentation for this and following points.)

The wartime agreement on separations procedures was embodied in the 1947 *Manual of Separations*. The FCC refrained from endorsing the manual, but said it would not object to its use. Telephone rates were set on the basis that non-traffic-sensitive exchange capital was allocated to interstate toll service according to the relative use of telephones as measured by the "subscriber line use" (*SLU*), where  $SLU = (\text{minutes of interstate use}) / (\text{total minutes of use})$ .

AT&T acceptance of the new accounting and separations procedures undoubtedly was based on its appreciation of the changed regulatory environment arising from the establishment of the FCC. Before 1934, interstate telephone service was essentially unregulated, and it made sense to keep expenses in state jurisdiction and revenues out of it. As the FCC gained influence and AT&T's allowable interstate rate of return declined, AT&T lost the incentive to keep its rate base in state jurisdiction.

AT&T therefore acceded to the federal government's wartime needs and the state regulators' needs for toll-rate uniformity. After all, the structure of telephone rates was not a major issue in a unitary system. Rates henceforth would be based on station-to-station accounting, but AT&T preserved its internal board-to-board accounting, using sep-

arations procedures to convert the figures from one model to the other.

In response to a 1950 FCC inquiry into interstate rates, AT&T proposed an alteration of the 1947 *Manual* that would have shifted more of the local telephone plant into the interstate rate base, and avoided or moderated a fall in interstate rates. The national organization of state regulatory commissioners (NARUC) strongly supported the plan since it would have provided the opportunity to reduce intrastate rates. The FCC however rejected it as being inconsistent with *Smith v. Illinois Bell* on the grounds "that its adoption would have the effect of introducing an arbitrary method whereby interstate services subject to Federal jurisdiction would, in effect, be subsidizing services beyond that jurisdiction." The FCC seems to have argued that *SLU* was the "correct" way to allocate costs between local and toll services.

The NARUC sought redress through Senator Earnest W. McFarland, the Republican majority leader and chairman of the Communications Subcommittee of the Senate Interstate Commerce Committee. It appealed to him at its 1950 convention in Phoenix, Arizona, the senator's home state. He responded with a letter to the FCC in which he expressed his dismay at the Commission's apparent willingness to "shift the load from the big user to the little user; from the large national corporations which are heavy users of long distance to the average housewife and business or professional man who do not indulge in a great deal of long distance." Noting the growing disparity between interstate and intrastate toll rates for comparable calls, the senator said, "I am not in a position to pass upon the question as to whether the remedy suggested by NARUC is the proper one but I am certain that something should be done—and at once."

The FCC either misjudged or ignored the intent of Senator McFarland's letter in its reply. It sent him a long summary of the history of separations replete with facts and figures in which it characterized the disparity in toll rates as "natural," and asserted that it was fulfilling its legal mandate to regulate interstate rates only. Senator McFarland re-

plied sharply: "I believe that the Commission's six-page reply takes a strictly technical attitude toward the whole problem rather than the broad, constructive viewpoint required by the Communications Act.... Frankly, the Commission's reply is disappointing to me and to my colleagues whose interest and concern occasioned my original letter to you."

The FCC promptly reopened negotiations with AT&T resulting in a revision of separations procedures that shifted enough revenue requirements to interstate operations to justify two interstate rate increases, not decreases, in the next two years. These were not only the first interstate rate increases granted since the FCC was created, they also took place at a time when the trend of technology was reducing the cost of long-distance service. The toll rate disparity to which Senator McFarland had directed the FCC's attention was sharply reduced. The FCC enforced cost allocations in which—by its own admission—long-distance revenues were used to subsidize local service.

When Long Lines' earnings rose in 1955, the FCC negotiated another revision of the 1947 *Manual* that followed the lines of the plan rejected by the FCC five years earlier. The new revision shifted even more revenue requirements into interstate jurisdiction. A series of further revisions continued the process of shifting exchange plant into the interstate arena, demonstrating the lasting imprint of the agreement between Congress, state and federal regulators, and AT&T reached in the early 1950's.

The issue of accounting models arose again in the 1960's and 1970's in reference to different problems and clothed in different language. As potential competitors appealed to the FCC for access to parts of the interstate telephone market, the FCC became concerned about cross subsidization *among* interstate services. The ensuing debate about cost allocations between various Bell services pitted two theories against each other. The FCC opted for a system based on fully distributed cost, where joint costs are allocated to different services according to relative use, as measured by an analogue of *SLU*. This

clearly is station-to-station accounting under a more modern name. AT&T favored the use of long-run incremental costs, an equally clear extension of the board-to-board model of long-distance service. The FCC rejected the use of long-run incremental costs as too subjective, but the preceding discussion of separations shows that the actual use of fully distributed costs is no less arbitrary and subject to manipulation. (William Baumol, 1971; Leland Johnson, 1982, pp. 16 and 34)

The divestiture also raised the question of accounting models, albeit implicitly, since the telephone network was split up along board-to-board lines. AT&T and the other interexchange carriers furnish board-to-board long-distance service, now called interLATA service, while the Regional Holding Companies and their operating companies supply local (intraLATA) service. While some Casandras saw the immediate end of separations procedures and consequent steep rises in local rates, Congress was up in arms over this now traditional issue, and the FCC has—so far—fallen once again line. Current controversies over access charges preserve in new bottles the old wine of disputes over accounting models.

Where, then, does the current confusion over cross subsidies come from? Only under the board-to-board model is there a clear subsidy from long-distance to local service. And, as has been shown here, the FCC has rejected the use of that model for forty years. Using a game-theoretic definition (Gerald Faulhaber, 1975), there is no cross subsidy from long-distance to local service under station-to-station accounting (unless the FCC's statement of thirty years ago that *SLU* represents the true station-to-station cost allocation is still valid today). (See our forthcoming article.) Even though divestiture has brought board-to-board accounting out of the closet once again, it has not clarified the difference between the two accounting models.

Why does the confusion still exist? Is it just confusion stemming from inadequate analysis? Or does it serve larger purposes?

Instead of grappling with these important questions, let us return to the relation of history to theory. The need for historical analysis to clarify the relation between theory and observation should be clear. The predictions of economic theory may fail to express historical reality for many reasons. And the historical record itself may be confused to the point where it is unclear which predictions have been fulfilled. Careful historical analysis can be avoided only at the economist's peril.

# Economic History and Economics

By ROBERT M. SOLOW\*

I have in the back of my mind a picture of the sort of discipline economics ought to be—or at least the sort of discipline I wish it were. If economics were practiced in that way there would be nothing problematical about its reciprocal relationship with economic history. It would be pretty clear what it is that economic theory offers to economic history and what economic history offers to economic theory. I will try to describe what I mean below.

For better or worse, however, economics has gone down a different path, not the one I have in mind. One consequence, not the most important one, but the one that matters for this discussion, is that economic theory learns nothing from economic history, and economic history is as much corrupted as enriched by economic theory. I will come to that, too, later on.

You will notice that I am using strong language. I am prepared to admit right away that I may be dead wrong in my judgements. But there is no point in pussyfooting. Bluntness may lead to an interesting discussion. After all, no one would remember the old German Historical School if it were not for the famous *Methodenstreit*. Actually, no one remembers them anyway. (There must be a lesson in that.)

To get right down to it, I suspect that the attempt to construct economics as an axiomatically based hard science is doomed to fail. There are many partially overlapping reasons for believing this; but since that is not the topic under discussion today, I do not have to lay them out in an orderly way. I hope the following hodgepodge will convey what I mean.

A modern economy is a very complicated system. Since we cannot conduct controlled

experiments on its smaller parts, or even observe them in isolation, the classical hard-science devices for discriminating between competing hypotheses are closed to us. The main alternative device is the statistical analysis of historical time-series. But then another difficulty arises. The competing hypotheses are themselves complex and subtle. We know before we start that all of them, or at least many of them, are capable of fitting the data in a gross sort of way. Then, in order to make more refined distinctions, we need *long* time-series observed under *stationary* conditions.

Unfortunately, however, economics is a social science. It is subject to Damon Runyon's Law that nothing between human beings is more than three to one. To express the point more formally, much of what we observe cannot be treated as the realization of a stationary stochastic process without straining credulity. Moreover, all narrowly economic activity is embedded in a web of social institutions, customs, beliefs, and attitudes. Concrete outcomes are indubitably affected by these background factors, some of which change slowly and gradually, others erratically. As soon as time-series get long enough to offer hope of discriminating among complex hypotheses, the likelihood that they remain stationary dwindles away, and the noise level gets correspondingly high. Under these circumstances, a little cleverness and persistence can get you almost any result you want. I think that is why so few econometricians have ever been forced by the facts to abandon a firmly held belief. Indeed, some of Fortune's favorites have been known to write scores of empirical articles without once feeling obliged to report a result that contradicts their prior prejudices.

If I am anywhere near right about this, the interests of scientific economics would be better served by a more modest approach. There is enough for us to do without pretending to a degree of completeness and

\*Department of Economics, Massachusetts Institute of Technology, Cambridge, MA 02139.

precision which we cannot deliver. To my way of thinking, the true functions of analytical economics are best described informally: to organize our necessarily incomplete perceptions about the economy, to see connections that the untutored eye would miss, to tell plausible—sometimes even convincing—causal stories with the help of a few central principles, and to make rough quantitative judgments about the consequences of economic policy and other exogenous events. In this scheme of things, the end product of economic analysis is likely to be a collection of models contingent on society's circumstances—on the historical context, you might say—and not a single monolithic model for all seasons.

I hope no one here will think that this low-key view of the nature of analytical economics is a license for loose thinking. Logical rigor is just as important in this scheme of things as it is in the more self-consciously scientific one. The same goes for econometric depth and sophistication, maybe even more so. I mentioned "rough" quantitative judgment a moment ago, but that was only to suggest that the best attainable, in macroeconomics anyway, is not likely to be precise, if we are honest with ourselves and others. It would be a useful principle that economists should actually believe the empirical assertions they make. That would require more discipline than most of us now exhibit, when many empirical papers seem more like virtuoso finger exercises than anything else. The case I am trying to make concerns the scope and ambitions of economic model building, not the intellectual and technical standards of model building.

I claimed earlier that the natural relation between economics and economic history would be clear and straightforward if only economics were practiced in the fashion I have just sketched. Now I had better say what I meant. If economists set themselves the task of modeling particular contingent social circumstances, with some sensitivity to context, it seems to me that they would provide exactly the interpretive help an economic historian needs. That kind of model is directly applicable in organizing a historical narrative, the more so to the extent that the

economist is conscious of the fact that different social contexts may call for different background assumptions and therefore for different models.

The other direction of influence, what economic history offers to that kind of economic theory, is more interesting. If the proper choice of a model depends on the institutional context—and it should—then economic history performs the nice function of widening the range of observation available to the theorist. Economic theory can only gain from being taught something about the range of possibilities in human societies. Few things should be more interesting to a civilized economic theorist than the opportunity to observe the interplay between social institutions and economic behavior over time and place.

I am going to illustrate by referring to the work of W. H. B. Court, not merely because his book *The Rise of the Midland Industries* was on A. P. Usher's reading list when I took his course in the late 1940's. I choose Court for no better reason than that I happened to run across an obituary article about him in the *Proceedings* of the British Academy for 1982. (Since Court died in 1971, Fate did seem to be playing a hand.)

Here, for instance, is an excerpt from Court's volume on *Coal* in the U.K.'s official history of World War II.

Observers who found the conduct of the mineworkers puzzling assumed that, in the normal way, a man who finds himself faced with the possibilities of higher earnings will be prepared to put out extra effort to obtain them. An assumption about the conduct of an individual is as a rule, however, also an assumption of some sort about the society in which he lives and of which he is a member. The individual's demand for income, his views upon the getting and spending of money, are usually formed by the part of society which he is most in touch with. For most men the social code, whatever it may be in their time and place, is something which they accept as given and take over with little demur or questioning. Before one can assume that a demand for additional income existed

on the coalfields and could easily translate itself into extra work, one has to ask whether the mining community had those standards or those habits. If it did not, and if it was unable to develop them in a short time, then even a rapid rise of wage rates might bring about no appreciable change in the working habits of the industry.

In his own methodological writing, Court made the point explicitly that men "living as they do in different societies...make their decisions according to different schemes of values and according to the habits and structures of the society they find themselves living in." Therefore an economic historian should be an "observer and re-creator of the codes, loyalties and organizations which men create and which are just as real to them as physical conditions." Add to that a command over two-stage least squares and you have the kind of economic historian from whom theorists have most to learn, if only they are willing to try. I have naturally lit on this passage about the labor market because that is the branch of theory I happen to be engaged in right now, but no doubt the thought would apply equally well to consumer spending or rivalry among firms. I must promise myself, before I lecture again on wage bargaining, to ask my students to read the chapters on "The Wage Bargain" and "The Concept of the Minimum" in Court's *British Economic History, 1870-1914: Commentary and Documents*. I wonder what they will make of it.

So much for the normative. If you read the same journals I do, you may have noticed that modern economics has an ambition and style rather different from those I have been advocating. My impression is that the best and brightest in the profession proceed as if economics is the physics of society. There is a single universally valid model of the world. It only needs to be applied. You could drop a modern economist from a time machine—a helicopter, maybe, like the one that drops the money—at any time, in any place, along with his or her personal computer; he or she could set up in business without even bothering to ask what time and which place. In a little while, the up-to-date economist

will have maximized a familiar-looking present-value integral, made a few familiar log-linear approximations, and run the obligatory familiar regression. The familiar coefficients will be poorly determined, but about one-twentieth of them will be significant at the 5 percent level, and the other nineteen do not have to be published. With a little judicious selection here and there, it will turn out that the data are just barely consistent with your thesis adviser's hypothesis that money is neutral (or nonneutral, take your choice) everywhere and always, modulo an information asymmetry, any old information asymmetry, don't worry, you'll think of one.

All right, so I exaggerate. You will recognize the kernel of truth. We are socialized to the belief that there is one true model and that it can be discovered or imposed if only you will make the proper assumptions and impute validity to econometric results that are transparently lacking in power.

Of course there are holdouts against this routine, bless their hearts.

As I inspect current work in economic history, I have the sinking feeling that a lot of it looks exactly like the kind of economic analysis I have just finished caricaturing: the same integrals, the same regressions, the same substitution of *t*-ratios for thought. Apart from anything else, it is no fun reading the stuff any more. Far from offering the economic theorist a widened range of perceptions, this sort of economic history gives back to the theorist the same routine gruel that the economic theorist gives to the historian. Why should I believe, when it is applied to thin eighteenth-century data, something that carries no conviction when it is done with more ample twentieth-century data?

The situation reminds me of a story I once heard told by an anthropologist who had spent some months recording the myths and legends of a group of Apache in New Mexico. One night, just before she was scheduled to end her field work and depart, the Indians said to her: We have been telling you our legends all these months—why don't you tell us one of yours? The anthropologist thought fast and then responded brilliantly by telling the Indians a version of the story of Beowulf.

Years later she picked up a copy of an anthropological journal and found in the table of contents an article entitled "On the Occurrence of a Beowulf-like legend among the such-and-such Apache." If economic history turns into something that could be described as "The Occurrence of an Overlapping-Generations-like Legend among the Seventeenth-Century Neapolitans," then we are at the point where economics has nothing to learn from economic history but the bad habits it has taught to economic history.

Let me recapitulate. If the project of turning economics into a hard science could succeed, it would surely be worth doing. No doubt some of us should keep trying. If it did succeed, then there would be no difference between economics and economic history other than the source of data, no more than there is a difference between the study of astronomical events taking place now and those that took place in the Middle Ages. In this dispensation an economic historian is merely an economist with a high tolerance for dust or—what is rarer these days—a working knowledge of a foreign language.

There are, however, some reasons for pessimism about the project. Hard sciences dealing with complex systems—but possibly less complex than the U.S. economy—like the hydrogen atom or the optic nerve seem to succeed because they can isolate, they can experiment, and they can make repeated observations under controlled conditions. Other sciences, like astronomy, succeed because they can make long series of observations under natural but essentially stationary conditions, and because the forces being studied are not swamped by noise. Neither of these roads to success is open to economists.

In that case, we need a different approach. The function of the economist in this approach is still to make models and test them as best one can, but the models are more likely to be partial in scope and limited in applicability. "Testing" will have to be less mechanical and more opportunistic, encompassing a broader collection of techniques. One will have to recognize that the validity of an economic model may depend on the social context. What is here today may be gone tomorrow, or, if not tomorrow, then in ten or twenty years' time. In this dispensation there is a clear and productive division of labor between the economist and the economic historian. The economist is concerned with making and testing models of the economic world as it now is, or as we think it is. The economic historian can ask whether this or that story rings true when applied in earlier times or other places, and, if not, why not. So the economic historian can use the tools provided by the economist but will need, in addition, the ability to imagine how things might have been before they became as they now are. These are the sensitivities Court spoke of in the passage quoted above. I take it, naively perhaps, that they represent the comparative advantage of the historian.

In return, economic history can offer the economist a sense of the variety and flexibility of social arrangements and thus, in particular, a shot at understanding a little better the interaction of economic behavior and other social institutions. That strikes me as a meaningful division of labor. It was once suggested—by my kind of economist—that the division of labor is limited by the extent of the market. Perhaps what I have just been doing can be thought of as marketing.

# Clio and the Economics of QWERTY

By PAUL A. DAVID\*

Cicero demands of historians, first, that we tell true stories. I intend fully to perform my duty on this occasion, by giving you a homely piece of narrative economic history in which "one damn thing follows another." The main point of the story will become plain enough: it is sometimes not possible to uncover the logic (or illogic) of the world around us except by understanding how it got that way. A *path-dependent* sequence of economic changes is one of which important influences upon the eventual outcome can be exerted by temporally remote events, including happenings dominated by chance elements rather than systematic forces. Stochastic processes like that do not converge automatically to a fixed-point distribution of outcomes, and are called *non-ergodic*. In such circumstances "historical accidents" can neither be ignored, nor neatly quarantined for the purpose of economic analysis; the dynamic process itself takes on an *essentially historical* character. Standing alone, my story will be simply illustrative and does not establish how much of the world works this way. That is an open empirical issue and I would be presumptuous to claim to have settled it, or to instruct you in what to do about it. Let us just hope the tale proves mildly diverting for those waiting to be told if and why the study of economic history is a necessity in the making of economists.

Support provided for this research, under a grant to the Technological Innovation Program of the Center for Economic Policy Research, Stanford University, is gratefully acknowledged. Douglas Puffert supplied able research assistance. Some, but not the whole, of my indebtedness to Brian Arthur's views on QWERTY and QWERTY-like subjects is recorded in the References. I bear full responsibility for errors of fact and interpretation, as well as for the peculiar opinions abbreviated herein. A fuller version with complete references, entitled "Understanding the Economics of QWERTY or Is History Necessary?," is available on request.

## I. The Story of QWERTY

Why does the topmost row of letters on your personal computer keyboard spell out QWERTYUIOP, rather than something else? We know that nothing in the engineering of computer terminals requires the awkward keyboard layout known today as "QWERTY," and we all are old enough to remember that QWERTY somehow has been handed down to us from the Age of Typewriters. Clearly nobody has been persuaded by the exhortations to discard QWERTY, which apostles of DSK (the Dvorak Simplified Keyboard) were issuing in trade publications such as *Computers and Automation* during the early 1970's. Why not? Devotees of the keyboard arrangement patented in 1932 by August Dvorak and W. L. Dealey have long held most of the world's records for speed typing. Moreover, during the 1940's U.S. Navy experiments had shown that the increased efficiency obtained with DSK would amortize the cost of retraining a group of typists within the first ten days of their subsequent full-time employment. Dvorak's death in 1975 released him from forty years of frustration with the world's stubborn rejection of his contribution; it came too soon for him to be solaced by the Apple IIC computer's built-in switch, which instantly converts its keyboard from QWERTY to virtual DSK, or to be further aggravated by doubts that the switch would not often be flicked.

If as Apple advertising copy now says, DSK "lets you type 20-40% faster," why did this superior design meet essentially the same rejection as the previous seven improvements on the QWERTY typewriter keyboard that were patented in the United States and Britain during the years 1909-24? Was it the result of customary, nonrational behavior by countless individuals socialized to carry on an antiquated technological tradition? Or, as Dvorak himself once suggested, had there

been a conspiracy among the members of the typewriter oligopoly to suppress an invention which they feared would so increase typewriter efficiency as ultimately to curtail the demand for their products? Or perhaps we should turn instead to the other popular "Devil Theory," and ask if political regulation and interference with the workings of a "free market" has been the cause of inefficient keyboard regimentation? Maybe it's all to be blamed on the public school system, like everything else that's awry?

You can already sense that these will not be the most promising lines along which to search for an economic understanding of QWERTY's present dominance. The agents engaged in production and purchase decisions in today's keyboard market are not the prisoners of custom, conspiracy, or state control. But while they are, as we now say, perfectly "free to choose," their behavior, nevertheless, is held fast in the grip of events long forgotten and shaped by circumstances in which neither they nor their interests figured. Like the great men of whom Tolstoy wrote in *War and Peace*, "(e) very action of theirs, that seems to them an act of their own free will, is in an historical sense not free at all, but in bondage to the whole course of previous history..." (Bk. IX, ch. 1).

This is a short story, however. So it begins only little more than a century ago, with the fifty-second man to invent the typewriter. Christopher Latham Sholes was a Milwaukee, Wisconsin printer by trade, and a mechanical tinkerer by inclination. Helped by his friends, Carlos Glidden and Samuel W. Soule, he had built a primitive writing machine for which a patent application was filed in October 1867. Many defects in the working of Sholes' "Type Writer" stood in the way of its immediate commercial introduction. Because the printing point was located underneath the paper carriage, it was quite invisible to the operator. "Non-visibility" remained an unfortunate feature of this and other up-stroke machines long after the flat paper carriage of the original design had been supplanted by arrangements closely resembling the modern continuous roller-platen. Consequently, the tendency of the typebars to clash and jam if struck in rapid

succession was a particularly serious defect. When a typebar stuck at or near the printing point, every succeeding stroke merely hammered the same impression onto the paper, resulting in a string of repeated letters that would be discovered only when the typist bothered to raise the carriage to inspect what had been printed.

Urged onward by the bullying optimism of James Densmore, the promoter-venture capitalist whom he had taken into the partnership in 1867, Sholes struggled for the next six years to perfect "the machine." From the inventor's trial-and-error rearrangements of the original model's alphabetical key ordering, in an effort to reduce the frequency of typebar clashes, there emerged a four-row, upper case keyboard approaching the modern QWERTY standard. In March 1873, Densmore succeeded in placing the manufacturing rights for the substantially transformed Sholes-Glidden "Type Writer" with E. Remington and Sons, the famous arms makers. Within the next few months QWERTY's evolution was virtually completed by Remington's mechanics. Their many modifications included some fine-tuning of the keyboard design in the course of which the "R" wound up in the place previously allotted to the period mark "." Thus were assembled into one row all the letters which a salesman would need to impress customers, by rapidly pecking out the brand name: TYPE WRITER

Despite this sales gimmick, the early commercial fortunes of the machine, with which chance had linked QWERTY's destiny remained terrifyingly precarious. The economic downturn of the 1870's was not the best of times in which to launch a novel piece of office equipment costing \$125, and by 1878, when Remington brought out its Improved Model Two (equipped with carriage shift key), the whole enterprise was teetering on the edge of bankruptcy. Consequently, even though sales began to pick up pace with the lifting of the depression and annual typewriter production climbed to 1200 units in 1881, the market position which QWERTY had acquired during the course of its early career was far from deeply entrenched; the entire stock of QWERTY-

embodying machines in the United States could not have much exceeded 5000 when the decade of the 1880's opened.

Nor was its future much protected by any compelling technological necessities. For, there were ways to make a typewriter without the up-stroke typebar mechanism that had called forth the QWERTY adaptation, and rival designs were appearing on the American scene. Not only were there typebar machines with "down-stroke" and "front-stroke" actions that afforded a visible printing point; the problem of typebar clashes could be circumvented by dispensing with typebars entirely, as young Thomas Edison had done in his 1872 patent for an electric print-wheel device which later became the basis for teletype machines. Lucien Stephen Crandall, the inventor of the second typewriter to reach the American market (in 1879) arranged the type on a cylindrical sleeve: the sleeve was made to revolve to the required letter and come down onto the printing-point, locking in place for correct alignment. (So much for the "revolutionary" character of the IBM 72/82's "golf ball" design.) Freed from the legacy of typebars, commercially successful typewriters such as the Hammond and the Blickensderfer first sported a keyboard arrangement which was more sensible than QWERTY. Then so-called "Ideal" keyboard placed the sequence DHIATENSOR in the home row, these being ten letters with which one may compose over 70 percent of the words in the English language.

The typewriter boom beginning in the 1880's thus witnessed a rapid proliferation of competitive designs, manufacturing companies, and keyboard arrangements rivalling the Sholes-Remington QWERTY. Yet, by the middle of the next decade, just when it had become evident that any micro-technological rationale for QWERTY's dominance was being removed by the progress of typewriter engineering, the U.S. industry was rapidly moving towards the standard of an upright front-stroke machine with a four-row QWERTY keyboard that was referred to as "the Universal." During the period 1895-1905, the main producers of non-typebar machines fell into line by offering "the Universal" as an option in place of the Ideal keyboard.

## II. Basic QWERTY-Nomics

To understand what had happened in the fateful interval of the 1890's, the economist must attend to the fact that typewriters were beginning to take their place as an element of a larger, rather complex system of production that was technically interrelated. In addition to the manufacturers and buyers of typewriting machines, this system involved typewriter operators and the variety of organizations (both private and public) that undertook to train people in such skills. Still more critical to the outcome was the fact that, in contrast to the hardware subsystems of which QWERTY or other keyboards were a part, the larger system of production was nobody's design. Rather like the proverbial Topsy, and much else in the history of economies besides, it "jes' grewed."

The advent of "touch" typing, a distinct advance over the four-finger hunt-and-peck method, came late in the 1880's and was critical, because this innovation was from its inception adapted to the Remington's QWERTY keyboard. Touch typing gave rise to three features of the evolving production system which were crucially important in causing QWERTY to become "locked in" as the dominant keyboard arrangement. These features were *technical interrelatedness*, *economies of scale*, and *quasi-irreversibility* of investment. They constitute the basic ingredients of what might be called QWERTY-nomics.

Technical interrelatedness, or the need for system compatibility between keyboard "hardware" and the "software" represented by the touch typist's memory of a particular arrangement of the keys, meant that the expected present value of a typewriter as an instrument of production was dependent upon the availability of compatible software created by typists' decisions as to the kind of keyboard they should learn. Prior to the growth of the personal market for typewriters, the purchasers of the hardware typically were business firms and therefore distinct from the owners of typing skills. Few incentives existed at the time, or later, for any one business to invest in providing its employees with a form of general human capital which so readily could be taken

elsewhere. (Notice that it was the wartime U.S. Navy, not your typical employer, that undertook the experiment of retraining typists on the Dvorak keyboard.) Nevertheless the purchase by a potential employer of a QWERTY keyboard conveyed a positive pecuniary externality to compatibly trained touch typists. To the degree to which this increased the likelihood that subsequent typists would choose to learn QWERTY, in preference to another method for which the stock of compatible hardware would not be so large, the overall user costs of a typewriting system based upon QWERTY (or any specific keyboard) would tend to *decrease* as it gained in acceptance relative to other systems. Essentially symmetrical conditions obtained in the market for instruction in touch typing.

These decreasing cost conditions—or *system scale economies*—had a number of consequences, among which undoubtedly the most important was the tendency for the process of intersystem competition to lead towards de facto standardization through the predominance of a single keyboard design. For analytical purposes, the matter can be simplified in the following way: suppose that buyers of typewriters uniformly were without inherent preferences concerning keyboards, and cared only about how the stock of touch typists was distributed among alternative specific keyboard styles. Suppose typists, on the other hand, were heterogeneous in their preferences for learning QWERTY-based “touch,” as opposed to other methods, but attentive also to the way the stock of machines was distributed according to keyboard styles. Then imagine the members of this heterogeneous population deciding in random order what kind of typing training to acquire. It may be seen that, with unbounded decreasing costs of selection, each stochastic decision in favor of QWERTY would raise the probability (but not guarantee) that the next selector would favor QWERTY. From the viewpoint of the formal theory of stochastic processes, what we are looking at now is equivalent to a generalized “Polya urn scheme.” In a simple scheme of that kind, an urn containing balls of various colors is sampled with replacement, and every drawing of a ball of a specified color results

in a second ball of the same color being returned to the urn; the probabilities that balls of specified colors will be added are therefore increasing (linear) functions of the proportions in which the respective colors are represented within the urn. A recent theorem due to W. Brian Arthur et al. (1983; 1985) allows us to say that when a generalized form of such a process (characterized by unbounded increasing returns) is extended indefinitely, the proportional share of one of the colors will, with probability one, converge to unity.

There may be many eligible candidates for supremacy, and from an *ex ante* vantage point we cannot say with corresponding certainty which among the contending colors—or rival keyboard arrangements—will be the one to gain eventual dominance. That part of the story is likely to be governed by “historical accidents,” which is to say, by the particular sequencing of choices made close to the beginning of the process. It is there that essentially random, transient factors are most likely to exert great leverage, as has been shown neatly by Arthur’s (1983) model of the dynamics of technological competition under increasing returns. Intuition suggests that if choices were made in a forward-looking way, rather than myopically on the basis of comparisons among the currently prevailing costs of different systems, the final outcome could be influenced strongly by expectations. A particular system could triumph over rivals merely because the purchasers of the software (and/or the hardware) expected that it would do so. This intuition seems to be supported by recent formal analyses by Michael Katz and Carl Shapiro (1983), and Ward Hanson (1984), of markets where purchasers of rival products benefit from externalities conditional upon the size of the compatible system or “network” with which they thereby become joined. Although the initial lead acquired by QWERTY through its association with the Remington was quantitatively very slender, when magnified by expectations it may well have been quite sufficient to guarantee that the industry eventually would lock in to a de facto QWERTY standard.

The occurrence of this “lock in” as early as the mid-1890’s does appear to have owed

something also to the high costs of software "conversion" and the resulting *quasi-irreversibility of investments* in specific touch-typing skills. Thus, as far as keyboard conversion costs were concerned, an important asymmetry had appeared between the software and the hardware components of the evolving system: the costs of typewriter software conversion were going up, whereas the costs of typewriter hardware conversion were coming down. While the novel, non-typebar technologies developed during the 1880's were freeing the keyboard from technical bondage to QWERTY, typewriter makers were by the same token freed from fixed-cost bondage to any particular keyboard arrangement. Non-QWERTY typewriter manufacturers seeking to expand market share could cheaply switch to achieve compatibility with the already existing stock of QWERTY-programmed typists, who could not. This, then, was a situation in which the precise details of timing in the developmental sequence had made it privately profitable in the short run to adapt machines to the habits of men (or to women, as was increasingly the case) rather than the other way around. And things have been that way ever since.

### III. Message

In place of a moral, I want to leave you with a message of faith and qualified hope. The story of QWERTY is a rather intriguing one for economists. Despite the presence of the sort of externalities that standard static analysis tells us would interfere with the achievement of the socially optimal degree of system compatibility, competition in the absence of perfect futures markets drove the industry prematurely into standardization *on the wrong system*—where decentralized decision making subsequently has sufficed to hold it. Outcomes of this kind are not so exotic. For such things to happen seems only too possible in the presence of strong technical interrelatedness, scale economies, and irreversibilities due to learning and habituation. They come as no surprise to readers prepared by Thorstein Veblen's classic passages in *Germany and the Industrial Revolution*

(1915), on the problem of Britain's undersized railway wagons and "the penalties of taking the lead" (see pp. 126–27); they may be painfully familiar to students who have been obliged to assimilate the details of deservedly less-renowned scribblings (see my 1971, 1975 studies) about the obstacles which ridge-and-furrow placed in the path of British farm mechanization, and the influence of remote events in nineteenth-century U.S. factor price history upon the subsequently emerging bias towards Hicks' labor-saving improvements in the production technology of certain branches of manufacturing.

I believe there are many more QWERTY worlds lying out there in the past, on the very edges of the modern economic analyst's tidy universe; worlds we do not yet fully perceive or understand, but whose influence, like that of dark stars, extends nonetheless to shape the visible orbits of our contemporary economic affairs. Most of the time I feel sure that the absorbing delights and quiet terrors of exploring QWERTY worlds will suffice to draw adventurous economists into the systematic study of essentially historical dynamic processes, and so will seduce them into the ways of economic history, and a better grasp of their subject.

## CREDIT AND ECONOMIC INSTABILITY<sup>†</sup>

### Portfolio Choice and the Debt-to-Income Relationship

By BENJAMIN M. FRIEDMAN\*

The relationship between outstanding debt and economic activity has attracted growing attention in recent years. In the United States, the principal focus of this attention thus far has been the empirical finding that, over time horizons ranging from a calendar quarter to a year or two, the total outstanding indebtedness of all U.S. borrowers other than financial intermediaries bears as close a relationship to income and prices as does any of the more familiar monetary aggregates or the monetary base. (See, for example, the evidence in my earlier paper, 1983.) This finding has potentially important implications for the conduct of monetary policy, and since 1983 the Federal Reserve System's semiannual reports to Congress have specified a growth range for "domestic nonfinancial credit" along with the growth ranges for three monetary aggregates.

A perhaps even more interesting aspect of the aggregate debt-to-income relationship in the United States is that the simple ratio of the U.S. economy's domestic nonfinancial debt to its gross national product has shown essentially no time trend over a period measured not in years but in decades. This finding bears potentially important implications for fiscal policy, especially in an era of federal budget deficits that are large enough to increase rapidly the federal government's out-

standing indebtedness in relation to *GNP*.<sup>1</sup> It is puzzling, however, in that many of the factors that familiar theory suggests would determine an economy's proclivity to finance its activity by issuing debt (for example, aggregate risk levels, tax rates, and bankruptcy arrangements) have changed dramatically over the decades during which the U.S. domestic nonfinancial debt ratio has remained approximately flat.

Any potential explanation for this phenomenon must, of course, focus on the behavior of lenders (debt holders) or borrowers (debt issuers), or both. The object of the research summarized in this paper is to see whether the behavior of investors in the U.S. financial markets could plausibly account for the economy's relatively stable debt-to-income ratio. This question turns on whether investors treat debt and other assets as close or distant substitutes in their portfolios. To anticipate, analysis of financial assets' respective risk properties indicates that debt and equity are indeed sufficiently distant substitutes for lenders' behavior to be a plausible source of the constraint confining the debt-to-income ratio within relatively narrow limits. At the same time, nothing in this finding precludes the possibility that borrowers' behavior could also be an equally or even more important part of the overall explanation.

#### I. Asset Risk and Asset Substitutability

The key link to lenders' behavior exploited here is the well-known fact that the U.S.

Sloan Foundation for research support.

<sup>1</sup>The federal government's debt ratio declined (as is usual in peacetime) from a peak of 1.03 in 1946 to a low of .25 in 1974. At year end 1980, it was still .27; by year end 1984, it had risen to .37.

economy's total wealth-to-income ratio has been essentially trendless for many decades (see Raymond Goldsmith, forthcoming), as would be implied by the life cycle model of saving under standard conditions describing a mature (albeit growing) economy. Over substantial periods of time, therefore, a stable debt-to-income ratio is equivalent to a stable share of debt assets in the economy's aggregate portfolio. In terms of familiar portfolio theory, if investors' behavior is imposing this constraint, then the relevant substitution elasticities must be small (in absolute value) in comparison with the corresponding wealth and/or income elasticities. Whether in fact they are so is an empirical question.

According to the standard theory describing the portfolio behavior of risk-averse investors, the relevant asset substitutabilities that matter here depend on investors' perceptions of the risk associated with holding debt and other assets. Investors' willingness to hold different assets depends on their assessments of the respective risks to which holding these assets exposes them, and their treatment of some assets as substitutes for others in their portfolios likewise depends on the relationships they perceive among the associated risks to holding these assets as well as others. If two assets expose holders to essentially the same set of risks, investors typically treat the two as close substitutes and allocate their portfolios accordingly. Assets subject to quite disparate risks are typically more distant substitutes, or perhaps even complements.

The basic framework of analysis used here is the familiar discrete-time theory relating risk-averse portfolio choice to expected asset returns. The investor's single-period objective, given initial wealth  $W_t$ , is to choose a vector of asset holding proportions  $\alpha_t$ , satisfying  $\alpha_t' \mathbf{1} = 1$ , to maximize expected utility  $E[U(\tilde{W}_{t+1})]$ . Under the conditions that  $U(W)$  is any power or logarithmic function (so that the Pratt-Arrow coefficient of relative risk aversion is constant), that the investor perceives the vector of real net asset returns  $\mathbf{r}_t$  to be distributed normally (or lognormally) with expectation  $\mathbf{r}_t^e$  and variance-covariance

structure  $\Omega_t$ , and that no available asset is riskless in real terms, solution of this problem yields

$$(1) \quad \alpha_t^* = B_t(\mathbf{r}_t^e + \mathbf{1}) + \pi_t,$$

where

$$(2) \quad B_t = \left\{ \frac{-U'[E(\tilde{W}_{t+1})]}{W_t \cdot U''[E(\tilde{W}_{t+1})]} \right\} \cdot [\Omega_t^{-1} - (\mathbf{1}'\Omega_t^{-1}\mathbf{1})^{-1}\Omega_t^{-1}\mathbf{1}\mathbf{1}'\Omega_t^{-1}];$$

$$(3) \quad \pi_t = (\mathbf{1}'\Omega_t^{-1}\mathbf{1})^{-1}\Omega_t^{-1}\mathbf{1}.$$

If the time unit is sufficiently small to render  $W_t$  a good approximation to  $E(\tilde{W}_{t+1})$  for purposes of the underlying expansion, then the first (scalar) term within brackets in (2) is simply the reciprocal of the constant coefficient of relative risk aversion.

Matrix  $B_t$  in (1), expressing the response of each proportional asset demand to movements in the expected real returns on that and other assets, contains the set of relative asset substitutabilities that determine how stable the respective shares of the typical investor's portfolio will be. The solution for  $B_t$  in (2) makes clear the central role of investors' risk perceptions in governing this behavior. The asset substitutabilities in  $B_t$  depend only on the investor's risk aversion and risk perceptions, here parameterized by a variance-covariance matrix  $\Omega_t$  that in general may vary over time.

## II. Substitutability among Financial Assets

Table 1, panel A, shows the variances and covariances, calculated from quarterly data for 1960–80, of the realized after-tax real per annum returns on three broad classes of U.S. financial assets that differ fundamentally from one another according to the risks associated with holding them. Short-term debt ( $S$ ) includes all assets bearing real returns that are risky, over a single year or calendar quarter, only because of uncertainty about inflation. Long-term debt ( $L$ ) is risky because of uncertainty not only about inflation but also about changes in asset prices di-

rectly reflecting changes in market interest rates. Equity ( $E$ ) is risky because of uncertainty about inflation and about changes in stock prices. (For details of the construction of these three after-tax real returns, see my 1984 paper.)

Table 1, panel B, indicates the implications of this observed 1960–80 covariance structure for investors' portfolio behavior by showing the transformation of  $\Omega$  given in (2), up to but not including multiplication by the reciprocal of the coefficient of relative risk aversion. Apart from the risk-aversion coefficient, these values for B indicate the marginal responses of the proportional portfolio allocations  $\alpha$  to changes in expected asset returns  $r^e$ . Hence they also indicate by what amount the structure of expected returns would have to change in order to induce any given shift in the composition of the typical investor's portfolio.

For plausible values of the risk aversion coefficient, the B values shown in Table 1 indicate that short- and long-term debt are fairly close substitutes for one another, but not for equity. For a relative risk-aversion coefficient of four,<sup>2</sup> for example, the increase in the expected short-term debt return (relative to the two other returns) that would be

B. Portfolio Response Matrix			
$\alpha_S$	1.57		
$\alpha_L$	-1.41	1.61	
$\alpha_E$	-.161	-.204	.365

Notes: See Table 1.

required to raise the short-plus-long debt share of the typical investor's portfolio by .01 is .63 percent. The corresponding required increase in the expected long-term debt return is .27 percent. Because the model is linear in expected returns, the analogous increase required to generate greater portfolio shifts are proportionally greater.

One potentially serious shortcoming of drawing such inferences on the basis of an unconditional sample variance-covariance structure is that it attributes too little information to investors by disregarding their knowledge, at each point in time, of the most recent realizations of asset returns and their principal determinants. During the 1960–80 period the after-tax real returns on all three classes of assets considered here exhibited substantial serial correlation. When returns are serially correlated, information about the most recent actual values is a useful ingredient in forming expectations about returns in the immediate future. Ignoring that information can lead to excessively large estimates of the uncertainty surrounding these expectations.

Table 2 presents a set of analogous results based on a procedure that takes much more careful account of what information investors did and did not have at any particular time. As of the beginning of each calendar quarter, investors presumably know the stated interest rates on short-term debt instruments, the current prices and the coupon rates on long-term debt instruments, the current prices and (approximately) the dividends on equities, and the relevant tax

<sup>2</sup>This value is about in the middle of the range of available empirical estimates. Irwin Friend and Marshall Blume (1975) suggested a value in excess of two, Sanford Grossman and Robert Shiller (1981) suggested four, and Friend and Joel Hasbrouck (1982) suggested six.

rates. The three uncertain elements that they must forecast over the coming quarter, in order to form expectations of the after-tax real returns on the three broad classes of assets considered here, are inflation, the capital gain or loss due to changing bond prices, and the capital gain or loss due to changing stock prices.

The procedure underlying the results reported in Table 2 represents investors as forming expectations of these three uncertain return elements, at each point in time, by estimating a linear regression model relating each element to past values of itself and the other two, using all data observed through the immediately preceding period.<sup>3</sup> In addition to providing forecast values of the three uncertain elements for the period ahead, the linear regression model at each point in time also directly indicates the variances and covariances associated with the forecasts derived in this way. After each period elapses, investors can then repeat the same procedure, incorporating the one new observation on inflation and on long-term debt and equity capital gains into the data used to reestimate the linear regression model to make forecasts for the next period.

Given the simple arithmetic connection between asset returns and these underlying uncertain elements, and given investors' presumed knowledge of the other elements comprising returns, these one-period-ahead forecasts of inflation and the respective capital gains on long-term debt and equity directly imply one-period-ahead forecasts of the after-tax real returns on all three classes of assets at each point in time. Similarly, the variances and covariances associated with the forecasts of inflation and the two capital gains directly imply the variances and covariances associated with the corresponding forecasts of the three asset returns.

Table 2, panel A, shows the means of these implied return variances and covariances for the 84 quarters of the sample. These values are smaller than the corresponding values shown in Table 1, indicating the importance of investors' having (and

using) information about recent actual returns.

Table 2, panel B, shows the transformation of this  $\Omega$  given in (2), again up to but not including multiplication by the risk-aversion reciprocal. The reduced uncertainty, in comparison with Table 1, makes investors more willing to re-allocate their portfolios in response to changes in expected returns. Even so, most of the asset substitutability is still between short- and long-term debt. With relative risk aversion again equal to four, the increases in the expected returns on short- and long-term debt required (individually) to raise the overall debt share of the typical investor's portfolio by .01 are .25 and .20 percent, respectively.

### III. Substitutability between Financial and Nonfinancial Assets

An important limitation of the analysis reported in Section II is its restriction to financial assets only. On a net basis, most of the total U.S. national wealth that has remained relatively stable in relation to U.S. economic activity consists of nonfinancial assets. Even for the household sector alone, year-end 1980 total wealth included \$2.8 trillion of residential real estate and \$1.0 trillion of consumer durables in addition to \$3.5 trillion of financial assets. If wealth holders are willing to substitute not just among financial assets but also between financial and nonfinancial assets, then the results presented in Section II presumably overstate the movements in the expected return structure required to change the share of debt in their portfolios, and hence also overstate the likely resulting stability of aggregate debt holdings in relation to either wealth or income.

Table 3 presents the results of applying the forecasting procedure underlying Table 2 to the after-tax real returns on the same three classes of financial assets together with two classes of nonfinancial assets, residential real estate ( $H$ ) and consumer durables ( $D$ ), based on annual data for 1964–81.<sup>4</sup> Apart

<sup>3</sup>See my 1984 paper for details of the estimated vector autoregression and the calculations based on it.

$\alpha_L$	-14.5	6.25			
$\alpha_E$	-4.49	-.628	.942		
$\alpha_H$	34.0	6.79	-2.95	168	
$\alpha_D$	-191	2.12	7.13	-206	387

Notes: See Table 1.

from the use of an annual time unit, the treatment of the uncertain elements of the financial asset returns is just analogous to that described in Section II. In order to generate forecasts of the respective returns on housing and durables, however, the forecasting equation here also includes the change in the constant-quality housing price index and the change in the implicit price deflator for durables.

Not surprisingly, given the role of inflation in making asset returns uncertain, the resulting variance-covariance matrix shown in panel A, Table 3, indicates that both categories of nonfinancial assets are less risky in real terms than any of the three financial assets. More importantly for the purposes of the analysis here, the transformation of this variance-covariance structure shown in panel B indicates that the implied responsiveness of portfolio allocations to changes in expected returns is far greater than suggested

by the analysis in Section II of financial assets alone. With relative risk aversion equal to four, the increase in the expected short-term debt return (again, relative to all other returns) required to raise the total debt share of the typical investor's portfolio by .01 is only .025 percent. A comparison of the elements in the first column of the matrix makes clear that more than all of this portfolio re-allocation occurs at the expense of the share invested in durables. Because of the cross effects of the substitutability of short-term debt with both durables and long-term debt, however, the corresponding movement in the expected long-term debt return required to raise the total debt share by .01 is a decline of .48 percent.

#### IV. Conclusions

Whether or not investors' behavior can plausibly account for the U.S. economy's trendless debt-to-income ratio depends crucially on the proper treatment of wealth holding in nonfinancial forms. Among financial assets only, the substitutability of debt and equity securities is sufficiently limited that very large movements in expected return differentials—movements so large as presumably to elicit offsetting responses from borrowers—would be required to induce major changes in the debt share of investors' aggregate portfolio. Given the long-run stability of the economy's wealth in relation to income, this lack of asset substitutability along the relevant dimension also implies a stable debt-to-income ratio.

By contrast, a parallel analysis applied to financial and nonfinancial assets together suggests that only quite modest movements in the structure of expected returns would suffice to induce even very large changes in the debt share of total assets, and hence in the aggregate debt-to-income ratio. The main reason for this result is the close substitutability of short-term debt and consumer durables implied by the respective risks associated with these two assets' after-tax real returns.

Especially since the key substitutability on which this difference hinges is to durables, rather than housing, the most sensible inter-

taxes, and changes in the Census Bureau constant-quality price index, using Robert Barro and Chaipat Sahasakul's (1983) average marginal income tax rate series. The nominal (untaxed) return on durables combines the BEA service value estimate and changes in the relevant BEA deflator. In both cases the corresponding real return follows from subtracting the percentage change in the consumer price index. Use of an annual time unit in this part of the analysis reflects the unavailability of several of these series on a quarterly basis.

pretation of these results is probably to discount the findings including nonfinancial assets and conclude that the portfolio behavior of risk-averse investors can plausibly account for a stable debt share of assets, and hence also (given the stability of wealth in relation to income in the United States) the observed stable debt-to-income ratio. One reason for drawing this conclusion is simply that asset-type considerations of risk and return alone probably do not constitute an adequate description of the demand for consumer durables. In a more fully developed description of that demand, the willingness to substitute holdings of short-term debt instruments for ownership of consumer durables would no doubt be much more limited. A second reason is that, to a far greater extent than in the case of return indexes for aggregates of financial assets (or even housing), the variation of the return index for the aggregate of all consumer durables presumably understates the risk associated with any individual's holding. A more accurate representation of that risk would also probably indicate less correlation with other asset risks, hence less substitutability for other assets, and hence less responsiveness of asset demands to changes in relative returns.

With this qualification, therefore, the behavior of lenders in the U.S. financial market does exhibit characteristics that could account for the observed stability of the economy's aggregate debt-to-income ratio over long periods of time. This conclusion, however, in no way precludes the behavior of

borrowers being as important, or more so, in explaining this phenomenon. That possibility remains a subject for future research.

# Stability and Instability in the Debt-Income Relationship

By ROBERT POLLIN\*

Over the recent past, economists have increasingly pursued research on the question of financial instability and financial crisis, reflecting, of course, the growing seriousness of these issues in the real world, both domestically and internationally. One important aspect of this research has been the effort to establish a set of empirical relationships through which tendencies toward instability and crisis may be accurately observed, and thus better understood. This paper has a dual purpose: first, to consider empirical measures of financial activity in the U.S. economy, specifically the trend relationship between nonfinancial debt and *GNP*; then, based on the empirical discussion, to offer an approach toward understanding some of the sources of contemporary financial instability. In the latter aim, I pay particular attention to the issue of federal government deficits.

## I. Stock and Flow Measures of Nonfinancial Debt

In studies of the U.S. economy, one empirical relationship that has attracted considerable interest is that between the outstanding debt of the economy's nonfinancial sectors and *GNP*—the juxtaposition of the nonfinancial economy's accumulated stock of net liabilities and its ability to generate income and output. This relationship has been investigated most thoroughly by Benjamin Friedman (1982, 1984), who has identified two important aspects of it. First, Friedman has found a high degree of stability between the growth of total outstanding debt of the nonfinancial sectors and *GNP*. As can be seen in Figure 1, this total outstanding debt-*GNP* ratio ( $S_t$ ) has displayed

essentially no trend and only limited cyclical variation throughout the post-World War II period. In contrast with this stability of the total outstanding debt ratio, Friedman has also found that the outstanding debt ratios of the individual nonfinancial sectors (households, businesses, and government) has varied significantly and in divergent ways. This also can be seen in Figure 1.<sup>1</sup> In particular, we observe a substantial declining trend of outstanding federal government debt-*GNP* ( $S_g$ ), and a mirroring of this by a rising trend of the outstanding debt-*GNP* ratios for households ( $S_h$ ) and nonfinancial business corporations ( $S_c$ ).

Friedman correctly recognizes that, as yet, no adequate explanation of these empirical patterns has been formulated. Nevertheless, a useful place at which an analysis may begin is the pioneering effort of John Gurley and Edward Shaw (1957) to explain the long-term tendency toward stability of the total outstanding debt ratio  $S_t$  (they did not consider the movements of its component parts). Gurley and Shaw formulated a long-term growth model of a developing economy, beginning at the zero level for both *GNP* and outstanding debt. They made two key assumptions in the model: a stable growth rate of *GNP* (after controlling for short cycles), and a constant marginal propensity to issue net new debt relative to *GNP*. Based upon their assumptions, they showed that  $S_t$  in their hypothetical economy does become asymptotically stable as the economy matures. The formula they derived for producing this stable ratio in a mature economy is

$$(1) \quad S_t = f_t(1 + y)/y,$$

where  $y$  is the growth rate of *GNP* and  $f_t$  is the marginal propensity of the aggregate

nonfinancial sector to issue net new debt—this latter variable I specifically define as net aggregate debt *flows*-GNP and refer to as the aggregate “debt-financing” ratio. According to Gurley and Shaw, therefore, the basis for the stability of  $S_t$  in a mature economy is the underlying stability which they assumed for  $f_t$  and  $y$ .

What is remarkable about the actual stability of  $S_t$  throughout the postwar period, and especially since the 1960's, is that it has resulted not through conformity with the

FIGURE 2. DEBT-FINANCING RATIOS FOR U.S. NONFINANCIAL BORROWERS

Gurley-Shaw conditions (a stable  $f_t$  and  $y$ ) but, in fact, *despite the sustained violation of these conditions*. First, GNP growth has not been stable over the postwar period on a trend basis, neither in real or nominal terms. Rather, the growth trend for nominal GNP has been upward throughout the period, while with real GNP growth, the trend was upward from the mid-1950's to mid-1960's and downward thereafter. These patterns can be seen in Table 1, where data are grouped by cycles. In addition, and even more significant for present concerns, the aggregate debt-financing ratio  $f_t$  has also not been stable over the full postwar period. Until the mid-1960's,  $f_t$  was trendless, but since then it has risen sharply on a trend basis. This pattern can be seen on the top line of Figure 2. The lower lines of Figure 2 show that each of the three major borrowing sectors (the federal government, households, and nonfinancial corporations) have also experienced rising

TABLE 1—POSTWAR GNP GROWTH RATES

Cycles	Nominal Growth	Real Growth
1949-51	8.6	5.8
1952-55	4.9	3.2
1956-59	5.1	2.4
1960-66	6.5	4.6
1967-73	8.4	3.5
1973-79	10.5	2.8
1980-83	8.2	0.9

Note: Cycles are measured according to the ratio of actual to potential GNP, the “GNP gap” ratio. The rates are shown in percent.

debt-financing ratios on a trend basis since the mid-1960's. And while we do also observe inverse covariation here between the federal government's debt-financing ratio ( $f_g$ ) and those for households ( $f_h$ ) and non-financial corporations ( $f_c$ ), in this case the relationship holds only on a cyclical basis, not over the period as a whole.

Hence, the actual stability of the total outstanding debt ratio  $S_t$  since the 1960's has emerged out of a set of underlying phenomena quite contrary to those posited by Gurley and Shaw: that is, a stable  $S_t$  has resulted through a declining trend for real  $y$  and rising trends for nominal  $y$  and, most importantly,  $f_t$  (all debt ratios being calculated with nominal  $GNP$  as the denominator). In other words, considering the trends for  $S_t$  and  $f_t$ , the aggregate nonfinancial sector has been accumulating debt since the mid-1960's at a stable rate relative to  $GNP$  while, by contrast, the aggregate rate of debt financing has been rising. At the individual sectoral level, moreover, we observe a similar divergence between outstanding debt and debt-financing ratios:  $S_g$  moves in inverse covariation with  $S_h$  and  $S_c$ , while, on a trend basis,  $f_g$ ,  $f_h$ , and  $f_c$  vary directly. To obtain a clear understanding of financial market behavior in the contemporary U.S. economy, and particularly its tendencies toward instability, it seems apparent that these contrary patterns for the outstanding debt and debt-financing ratios need to be examined carefully.

## II. Reconciling the Divergent Trends

To explain the divergent patterns of  $S_t$  and  $f_t$ , there is a simple formal explanation. Referring to the Gurley-Shaw equation  $S_t = f_t(1+y)/y$ , it is evident that since  $y$ , the nominal growth rate of  $GNP$ , has been rising sharply since the mid-1960's, the ratio  $(1+y)/y$  will fall correspondingly over this period. Therefore  $f_t$  must rise along with  $y$  in order for  $S_t$  to remain constant. But this formal solution does not explicitly address the crucial substantive phenomenon affecting the divergent patterns of  $S_t$  and  $f_t$ —the asymmetric impact of inflation on the two ratios. Consider first  $S_t$ . Here the numerator

of the ratio, the stock of debt, remains fixed in nominal terms regardless of variations in the price level. The denominator, nominal  $GNP$ , is a flow variable however, and as such it varies in nominal terms directly with the price level. In an inflationary environment therefore, the nominal value of the debt stock remains fixed while  $GNP$  rises, so that  $S_t$  is biased downward. With  $f_t$ , by contrast, current-period flow values are in both numerator and denominator, and thus the impact of inflation on the ratio is neutral. It is therefore because of the sustained inflation since the 1960's that  $S_t$  has remained stable while  $f_t$  has risen.<sup>2</sup>

To explain the inverse covariation of  $S_g$  with both  $S_h$  and  $S_c$ , and the absence of similar trend relationships with the sectoral debt-financing ratios, we must focus upon financial conditions emerging out of World War II. During the war, the federal government accumulated a huge debt while concurrently restrictions were placed on private sector expenditure and borrowing. As a result, the government owed 71 percent of the total U.S. outstanding debt in 1945. With this figure as the starting point for the postwar period, a pattern of inverse covariation between  $S_g$  and both  $S_h$  and  $S_c$  necessarily emerges after the war as long as  $f_g$  is less than  $f_h$  and  $f_c$  (a condition which holds for virtually every postwar year until the mid-1970's). This inverse covariation will then necessarily continue until  $S_g$  settles at a level that reflects the government's current proportion of net new debt issues—that is, until the effects of wartime finance on the outstanding debt ratios have dissipated.

To illustrate this point further, Figure 3 shows the results of the following simulation exercise: the postwar period begins in 1946 with the actual proportions of debt outstand-

<sup>2</sup>To recognize this effect of inflation on debt ratios does not however point toward any particular causal hypothesis explaining the relationship between the rates of inflation and debt issuance since the mid-1960's. This complex question still requires much further investigation. I can however acknowledge here an important related accounting effect of inflation. See my 1984 paper for a brief critical review of the literature on this question.

FIGURE 3. SIMULATED OUTSTANDING DEBT RATIOS FOR U.S. NONFINANCIAL BORROWERS

ing for the federal government, households, and nonfinancial corporations and with  $S_t = 1.40$ . Trends over the entire postwar period for  $S_g$ ,  $S_h$ , and  $S_c$  are then generated assuming a constant nominal GNP growth rate of 10 percent, a stable  $S_t$  at 1.40, and constant proportional shares of net new debt issues for the three sectors. The values used in setting each sector's constant proportional share of net debt issues are their actual mean proportions over the postwar period. As can be seen in Figure 3, the simulated outstanding debt ratios replicate the actual patterns quite closely: we observe both the inverse covariation between the ratios beginning in the initial postwar years and the dissipation of that pattern by the mid-1970's. Hence, this exercise affirms that what is reflected in the actual trends of the sectoral outstanding debt ratios is the grafting of relatively stable proportions of debt issuance onto the skewed outstanding debt structure of the immediate postwar years. The observed inverse covariation of the actual sectoral ratios does not therefore reflect any corresponding inverse relationship in the sectors' rates of debt issuance over the postwar trend.

### III. Debt Ratios and Financial Activity

#### A. The Impact of Government Deficits

Frequently the debt ratios are examined in order to provide an empirical framework for analyzing the impact of rising federal government deficits. Almost always when this is done, attention is focused only on the outstanding debt ratios. In Friedman's work (especially 1984), where the debt ratios are analyzed most fully in this regard, the central concern is the rising value of the government's outstanding debt ratio  $S_g$  that will occur over the next four years through even the most conservative estimates of forthcoming government deficit levels. The implications of this pattern for Friedman are derived from his analysis of the debt ratios' behavior throughout the postwar period.

He first of all believes that the long-term stability of the total outstanding debt ratio  $S_t$  represents a fundamental equilibrium point for the economy: the continuation of this fixed ceiling for  $S_t$  becomes the major assumption in his analysis. Based on this assumption, an increase in one sector's debt ratio becomes possible only through a declining ratio for some other sector(s)—hence the inverse covariation between the sectoral ratios over the postwar period. From this perspective then, the postwar trend decline of  $S_g$  served to release scarce financial resources from the federal government, and thus to permit the household and corporate rates of debt issuance (their "reliance on debt") to rise. In Friedman's view, we observe this increasing reliance on debt by households and corporations through the upward trends for  $S_h$  and  $S_c$ . The prospect of a rising  $S_g$  over the next four years thus implies that, in the absence of a fully accommodating (and inflationary) monetary policy, the financial resources available to households and corporations will become increasingly scarce and costly. This is particularly harmful in Friedman's view because corporations have relied upon debt increasingly since the mid-1960's to finance investment spending. He believes investment growth will be constrained with  $S_g$  rising, and as a result, advances in productivity generated through increasing the capital stock will be inhibited.

### B. *A Critique and Reformulation*

While this perspective is internally consistent, it is misleading in several important ways due to its exclusive focus on the outstanding debt ratios. The problem is not simply that debt-financing patterns are overlooked; equally distorting is that the conceptual distinction between debt financing and debt accumulation is not recognized. When the debt-financing patterns are explicitly incorporated into the analysis, a significantly different, and I believe more valid, perspective on federal deficits becomes possible, as does a more accurate assessment of U.S. financial conditions in general.

First, once we recognize the phenomenon of debt financing as distinct from debt accumulation, it becomes clear that the financing ratios, not the outstanding debt ratios, measure rates of debt issuance, the reliance on debt as a source of finance during any given time period. Of course, the outstanding debt ratios reflect the financing patterns to some extent. However, as I have argued above, the behavior of these ratios is also skewed by the effects of wartime finance and inflation. While these effects may indeed alter the behavior of borrowers and lenders as well as the future value of the new debt, certainly they should not bear upon how the current period issuance of debt is measured.

Given this, it follows that the observed inverse covariation of  $S_g$  with  $S_h$  and  $S_c$  does not signify a corresponding inverse covariation in each sector's reliance on debt finance. In fact, as the debt-financing ratios show, the three sectors experienced similar patterns of debt issuance throughout the postwar period: stability through the mid-1960's as  $f_g$ ,  $f_h$ , and  $f_c$  were all trendless; and increasing debt issuance relative to *GNP* thereafter. From this perspective then, we perceive no necessity for the government's rate of debt issuance to fall in order for households' and corporations' debt issuance to increase.

An alternative view as to the capacity of the nonfinancial sectors in the aggregate to undertake increases in debt financing also emerges from this perspective. More specifically, with the total debt-financing ratio  $f$ , having risen since the mid-1960's, it appears

—contrary to the impression suggested by  $S_i$ —that no apparent limit has been defined as to how much net new debt the nonfinancial sectors can issue relative to *GNP*. This reinforces the idea that increasing debt financing by the federal government does not prevent other sectors from acting similarly.

The magnitude of the federal government's postwar financial activities also assumes different dimensions once debt-financing ratios are taken into account. By any measure, the current rate of issuance by the federal government is unprecedented for the postwar period. But it is not the case—as is inferred by considering solely the trend for  $S_g$ —that this behavior signifies the reversal of a long-term pattern of decreasing debt reliance by the government. Rather, it actually represents the continuation, albeit at an accelerated rate, of a trend that began in the 1960's toward increasing government debt financing. By this measure, in other words, we observe that the government's presence in financial markets—and its corresponding impact on macroeconomic behavior through deficit spending—has been rising, not falling during the past fifteen years.

Finally, the relationship between the nonfinancial corporations' reliance on debt financing and their capacity to enlarge the capital stock is also clarified by examining the debt-financing data. It is true, as the pattern of  $f_c$  implies, that nonfinancial corporations have relied increasingly since the mid-1960's on debt financing to undertake investment spending. But this increase in debt reliance has not been associated with rising rates of real fixed-investment growth. Rather fixed-investment growth for nonfinancial corporations was significantly higher in the years prior to the mid-1960's than afterward (mean values for real annual fixed investment growth were 5.4 percent between the cyclical peak years 1949–66 and 4.3 percent for 1966–83). Increasing debt financing by the corporations, in other words, has been associated with a *declining* fixed-investment growth rate. It is therefore not apparent that high rates of corporate debt financing will bring increasing rates of capital formation, or that decreasing rates of debt financing will necessarily retard investment growth.

### C. *Further Considerations on Financial Instability*

Clearly, an alternative perspective of contemporary U.S. financial conditions emerges when the debt-financing patterns are taken into account. Moving beyond the single question of federal deficits, this perspective can serve as a basis for clarifying several other issues linked to the problem of financial instability. First, what is most evident in observing the debt-financing ratios is that a significant change on the demand side of credit markets—an upward shift in aggregate reliance on borrowed funds—did emerge after 1966. This development, unobservable through the outstanding debt ratios, is nevertheless fully consistent with other important changes in the financial structure beginning in the mid-1960's: on the supply side, the growing importance of financial innovation and liability management; and more broadly, the emergence of increasingly serious "credit crunches" and other crisis episodes (see Albert Wojnilower, 1980). These latter phenomena are much less comprehensible if one begins with the conception that aggregate reliance on debt has been essentially stable over the past thirty-five years.

By recognizing the debt-financing and outstanding debt ratios as analytically distinct, we may also now distinguish two separate forces affecting the stability of the financial structure on the demand side: changes in the reliance on debt, and changes in the *debt burden*. While the debt-financing ratios are superior indicators of debt reliance, clearly the debt burden must be measured on the basis of the accumulated stock of debt.<sup>3</sup> Establishing this distinction in turn brings into focus one fundamental aspect of inflation's impact on the financial structure, an effect which arises through inflation's asymmetric impact on the stock and flow ratios. Because of this asymmetry, the nonfinancial sectors' increasing reliance on debt over the past twenty years has not engendered similar increases in their debt burdens. Thus, how-

ever else inflation may affect financial conditions, it exerts a stabilizing influence insofar as it reduces net borrowers' real debt burden. Similarly, disinflation (to say nothing of deflation) will exacerbate instability by increasing the real debt burden. These factors become particularly important if the nonfinancial sectors' reliance on debt continues to rise in the future while the inflation rate remains at a relatively low level. It follows also that to counter tendencies toward overindebtedness through means other than inflation will probably require that the nonfinancial sectors' debt-financing ratios be stabilized at a lower level than in recent years.

To explain the debt-financing ratios' upward trend thus emerges as a central problem. While I cannot even begin a systematic discussion of this issue here (I do attempt such with respect to nonfinancial corporations in my earlier paper), one important aspect of it can be highlighted as a point for further consideration. The data presented here show that the rise of  $f_t$  and its sectoral components has not occurred in association with increases in the growth rates for real investment or output, but rather with declining real growth for both. It therefore appears insufficient to explain the rise of debt financing through a standard neoclassical framework emphasizing price effects, specifically the declining real borrowing costs and/or debt burden which occurred through the 1970's. If these were the prime motivating forces, we would then expect the growth of real expenditure and output to rise along with the increase in debt financing. For similar reasons, it also appears inadequate to frame the problem in the manner of Hyman Minsky (1982) and Wojnilower, as an expression of a persistent boom psychology. Rather it seems that a more fruitful place to focus the analysis is at precisely the point stressed by Gurley and Shaw—the relationship between debt financing and income growth. Working from there, the increasing debt reliance would appear to have resulted primarily because of the declining capacity of real income growth—and the internal funds derived from income—to meet perceived expenditure needs.

<sup>3</sup> However, debt stocks themselves do not fully measure debt burdens, since interest payment obligations must be included as part of the burden.

# Private Credit Demand, Supply, and Crunches— How Different are the 1980's?

By ALBERT M. WOJNOWER\*

In the fall of 1980, I had the unusual privilege for a business economist of preparing a Brookings Paper on Economic Activity. In post-1950 U.S. business expansions and especially near business cycle peaks, I argued, aggregate private credit demand had been essentially interest rate inelastic and far in excess of the supply. As a result, downturns in credit use and general business activity had developed only after some blockage in the supply of credit—a sudden and unanticipated intensification of nonprice rationing, commonly labeled a “credit crunch.”

These often frightening crunches were triggered either by 1) credit or interest rate controls that sharply constricted the lending incentives or capacities of financial institutions, or 2) unanticipated default crises that had the same paralytic impact. Each such episode, however, prompted responses by the affected parties (borrowers, lenders, and regulators) to remove the “bottleneck” that had provoked the crisis. The consequent financial innovation, deregulation, and attendant broadening of the Federal Reserve's lender-of-last-resort functions greatly enlarged the supply of credit, intensified the inflationary potential of business upswings, and heightened the risk of a general financial collapse.

The plan here is to sketch the relevant experience subsequent to October 1980 when my earlier paper was presented. As with econometric models, the postsample observations do not fit as neatly as did the in-sample data. Nevertheless, I believe, the fundamental conclusions have stood up well.

## I. Credit Demand during Expansions

For those not accustomed to thinking of aggregate credit demand as innately huge

and inelastic, the stubborn persistence of rapid credit growth and business activity in the face of the 1979–80 financial turmoil, as well as their virtually instant revival following the classic crunch induced by the short-lived credit controls of 1980, was a great surprise. The controls were imposed on March 14; on July 3, the last remaining restrictions were abolished. During the spring, there was a sharp economic recession and drop in interest rates, but both ended in July. By the close of 1980, interest rate levels had already surpassed the new records they had established early in the year. From December 1980 through October 1981, notwithstanding a dramatic and persistent reduction in inflation, the bank prime loan rate hovered almost uninterruptedly in the 18–20 percent range.

But credit demand was not deterred. Business loan expansion, much of it to support sizable increases in real fixed investment, achieved and maintained record growth rates into the opening months of 1982, far beyond the onset of recession in midsummer 1981. The growth in loans slowed appreciably only when default calamities began to erupt in the spring of 1982. Consumer borrowing growth also accelerated dramatically, although it failed to regain previous peak rates. Some retardation in growth began during the spring of 1981, but no material setback occurred until late 1981, well after the business cycle crest in July.

Only the behavior of mortgage credit departed radically from earlier experience. In previous business cycles, mortgage credit growth had accelerated well along into the general business upswing, but in the 1980–81 recovery it began to diminish within a few months. This weakness, however, did not reflect any substantial decline or rate elasticity in mortgage demand, but rather some crippling constraints on the lenders (described in Section II below). In the 1983–84 upswing, by which time the blockages in

\*Managing director and chief economist, The First Boston Corporation, Park Avenue Plaza, New York, NY 10055.

mortgage supply had been removed, mortgage generation recovered strongly and remained vigorous, notwithstanding a level of effective interest rates that, in view of reduced general and house-price inflation, was probably higher yet than in 1980–81.

The business upturn that began in late 1982 provides a remarkable demonstration of how strong credit demand can be even in depressed circumstances. The initial thrust of the business recovery clearly depended on surging demand for homes and cars, two notoriously credit-dependent sectors. An enormous burst of private credit growth began at a time when consumer and producer prices had remained essentially unchanged for some six months, and while mortgage, consumer, and business loan interest rates—and unemployment—all exceeded 10 percent!

In 1983 and 1984, the expansion of private (and federal) credit continued apace, although nominal interest rates generally rose and inflation expectations (albeit not the measured rate of inflation) allegedly abated. No doubt there exist interest rate levels high enough to curb private credit demand, but the experience of the 1980's to date, featuring good times and bad, and intervals of double-digit as well as zero inflation, suggests they lie well above the range of recent observation.

The proliferation of floating-rate lending has further attenuated whatever rationing power interest rates may exert. For at least several years now, some 75 percent or more of large over-one-year bank loans have been made at variable rate. But lately the major part of corporate bond issuance also has become variable-rate and/or short-term in character. Fixed-rate issues with over ten years to maturity are a vanishing breed, comprising only 21 percent of nonconvertible corporate bond issuance in 1984, down from about 35 percent in 1981–83, and 60 percent or more in earlier years.<sup>1</sup> In my earlier paper

I noted the apparently indestructible “optimism” of industrial executives and institutional investment managers that interest rates will fall. Perhaps lenders now see more need for protection against possible interest rate increases, but business borrowers apparently remain confident that rates will decline.

The home mortgage market is another sector in which floating rates have just recently come to predominance. In recent months, some two-thirds of new home mortgages have carried variable rates. But in mortgages, this seems to be mainly at the lender's rather than the borrower's initiative. Consumers must be “bribed” to accept variable rates. The essential “sweeteners” include a lower “base” rate, sizable initial-year discounts, caps on rate increases and/or levels, provisions for “negative amortization” to hold down monthly payments, and so on. This accords with my 1980 view that the borrowing behavior of households, though not particularly interest rate sensitive, is much more restrained than that of business firms and financiers.

The great majority of variable rate loans of all kinds is indexed to a one-year or shorter-term interest rate. What role remains for interest rates in rationing credit demand when most credit is either short-term, or indexed to a short-term interest rate? Do long rates (and the yield curve) still matter if hardly any private borrowing takes place at these rates? Do even short rates matter much? Short-term changes in short rates should affect only short-horizon decisions.

In actuality, interest rate fluctuations now appear to exert their principal impact by altering the cash positions of floating-rate borrowers. Mortgage debtors, however, are cushioned against rate increases by indexing lags, caps, and negative amortization. Among business debtors, rises in rates seem merely to strengthen the consensus that rates must come down soon. Thus firms always are inclined to hold on just a little longer rather than to retrench. The rising rates simply add an involuntary (by definition, interest-inelastic) component to credit demand to finance the unexpectedly higher interest payments.

The merry-go-round spins until insolvency looms. To become effective, monetary re-

straint must threaten widespread defaults. Only lately is it becoming generally recognized that the floating-rate mode converts interest rate risk to credit risk. (See my earlier paper, p. 296. For a formal treatment, see Anthony Santomero, 1983.)

## II. The Supply Side

An important reason why lenders are eager to innovate is their awareness of the chronic excess demand for credit. Lenders wish to be deregulated so as to be free of constraints that prevent them from lending more. During 1980–82, new deregulation was relatively slow, but dramatic further steps, particularly the introduction of money market deposit and Super-NOW accounts with no interest rate restrictions, took place in late 1982 and early 1983. The credit boom of 1983–84 is one consequence.

Indeed, from the standpoint of the individual depository institution, the recent abolition of most interest rate controls on consumer deposits has made more rapid expansion a matter of necessity as well as choice. An earnings squeeze has been created from which “growing your way out by lending more” seems the only hope of escape. But of course the intensified competition for loans narrows profit margins further, and this at a time when hostile capital markets leave many banks and thrifts more than ever dependent on internal funds for strengthening their capital. So long as interest rate ceilings held deposit rates at below-market levels, depository institutions had an easier way out. The cushion provided by a reliable stock of cheap deposit “raw material” gave them the option of building up earnings and capital by means of a “play safe” policy of investing only in relatively low-yield safe loans and government securities. But in the new environment, safety is a luxury most lenders cannot afford.

In the large, of course, the total quantity of credit remains in principle determined (intentionally or not) by Federal Reserve policy. But the Federal Reserve is a rather complex “endogenous” variable. Such is especially the case whenever, as has been the predominant view for at least twenty-five

years, interest rates are regarded as high. When rates are thought to be high, or when the financial system seems threatened by defaults, the Federal Reserve will be relatively timid in tightening. If, concurrently, lenders have reason to become more aggressive, they in effect lead the authorities to what by hindsight becomes recognized as overly expansionary policy.

As the last recession drew to a close in late 1982, it was widely conceded that the financial structure was in debilitated condition. The banking system, thrift institutions, parts of the securities industry, and many businesses had recently brushed disaster. Not only should the demand for credit have been weak, but also the supply. Domestic borrowers should have experienced credit access problems similar to those of the *LDCs*. Yet by mid-1983, the growth rate of domestic private debt resumed its prerecession pace. By year end, it was growing at a rate previously reserved largely for the “elderly,” inflation-ridden stages of business expansion.

Dramatic changes occurred in the character of many credit markets. There was a prodigious outburst of bank lending to finance mergers and acquisitions, particularly so-called “leveraged buyouts.” Other types of business loans also soared. In the first half of 1984, net debt of nonfinancial corporations enlarged at a \$181 billion annual rate; the previous peak year (1981) was \$103 billion. This does not include the burgeoning of credit guarantees issued by banks, for which there are no statistics.

Explosive growth also took place in consumer credit. The dollar amount of the increase for the first half of 1984 (seasonally adjusted) exceeded any previous full year's gain. In the face of significant increases in the general level of interest rates during 1983 and the first half of 1984, the intense lender competition actually forced installment credit charges down; as of mid-1984, they were still near their post-1980 lows.

It was, however, the single-family home mortgage market that was most radically transformed. In 1980–82, as indicated before, both the lending incentive and capacity of thrift institutions had been crippled. Because short rates were chronically and atypi-

cally higher than long rates, using short-term funds to finance mortgage lending was unprofitable. Also, thrift deposit rates were still regulated in such a way that they could not be relied upon to remain, and often in fact were not, fully competitive with alternatives such as money market funds. Furthermore, although mortgage rate ceilings set by state usury laws had been preempted by federal legislation in March 1980, the states had been given three years to reinstitute rate ceilings if they chose. Thus it was uncertain whether the provisions of high rate or floating-rate mortgages would stand up. At many institutions, the mortgage rates posted were those at which they *might* lend to preferred clients, rather than those at which they invited business.

All this had passed by the beginning of 1983. Short rates were below long rates, and the relevant restrictions on deposit rates had been or shortly were to be abolished. Legal limits on mortgage rates were effectively defunct. Many would-be borrowers might have been unable, however, to meet income tests at the prevailing rates. Lenders responded resourcefully. Partly reflecting a legal mandate that suddenly became commercially useful, they became more enthusiastic about counting second incomes (usually wives'). Also income tests were eased, directly as well as indirectly. Substantial rate discounts are widely offered for the first year or two, which help bring down the initial monthly payments into qualifying range. In a dramatic turnabout, the growth rate of home mortgage debt surged from a near-record low of 4 percent in the second half of 1982 to a 12 percent rate of gain only a year later, a pace that was still being maintained in the third quarter of 1984, almost two years into the business upswing (see Figure 1).

The impetus toward more aggressive lending is by no means confined to the large institutions. Under deregulation, new or unknown banks may and do offer higher deposit interest rates than well-known banks. The unknown bank may have localized high-return outlets not accessible to larger lenders; or it may be willing to take greater credit risk or accept lower markups; or it may have (or thinks it has) lower costs. The

FIGURE 1. GROWTH RATES OF PRIVATE NON-MORTGAGE CREDIT AND PRIVATE MORTGAGE CREDIT (Semiannually seasonally adjusted annual rates. Shaded areas are business recessions.)

result is the more intensive exploitation of lending opportunities as well as the narrowing of margins and easing of credit standards (nonprice terms).

Conditions in the credit industry have many instructive analogies with the newly deregulated airline business. One is that new "fly-by-night" airlines can prosper because their FAA certification is equivalent to that of established lines; fly-by-night banks can prosper on the strength of their official deposit insurance. At a price, many people probably would be willing to fly uncertificated planes and to deposit funds in uninsured banks; but the general public (wisely) is unwilling to tolerate the social consequences of plane or bank crashes.

For an individual airline, the competitive response to deregulation, short of going out of business, is to price so as to fly fuller planes more continuously. That, subject to technological and environmental constraints, is presumably a good thing. But do we wish financial institutions always to be loaned to the hilt? A lesser rather than a higher rate of credit expansion is implied by the national goal of price stability.

### III. Crunches and Crises

During the early 1980's, I conclude, the credit markets have continued to be characterized by an explosive mixture of chronic excess demand and rapidly expanding supply. Yet were that the whole story, only a credit crunch—a major interruption in credit supply—could have appreciably retarded private credit expansion and triggered a recession. Unquestionably, however, the business downturn that set in during the summer of 1981 was unheralded by any credit crunch. Although the later succession of credit crises that developed in May-August 1982, summarized below, may warrant the crunch label, by then the recession was already long under way.

How could this have happened? As already indicated, the explanation probably lies mainly in the anomalous behavior of mortgage credit in 1980-81. There was a crunch in mortgage credit, but not in other types of credit. As a result, the recovery in homebuilding began to be aborted almost immediately and neither aggregate credit expansion nor the economy ever regained full momentum. If subsequent mortgage-market innovation and deregulation have permanently enhanced the viability of mortgage generation under financial adversity, as I believe they have, the 1981 "quiet" business cycle crest without a general credit crunch will not become typical.

In the absence of credit supply squeezes due to regulatory constraints, lender "growthmanship" has, as was to be expected, multiplied the "accidents" that activated lender-of-last-resort support. While some crises of the earlier 1970's (such as the Penn Central, Franklin National Bank, and Hers-

tatt debacles), provoked credit crunches and recessions, reaction to subsequent major default problems demonstrated that, by 1980 if not sooner, the public had come to take for granted that the authorities would not allow any sizable financial actor to default. As a result, although several recent shocks have carried ample potential for catastrophe, their adverse macroeconomic impact has been mild.

One such "accident" was the May 1982 collapse of Drysdale & Co., a minor government securities dealer. Although the firm was small, the amounts and ripple effects were large. One of several dangerous consequences was to cloud the lender's claim on government security collateral used in repurchase agreements, the principal form of credit used by dealers to finance their positions. Had not the Federal Reserve intervened with alacrity, the functioning of the government securities market would have been seriously impaired.

Soon after came the Penn Square disaster. This was the failure of a smallish Oklahoma bank that had managed to sell billions of questionable loans to major banks and was also a depository for a number of other small banks. The regulators attempted to limit their involvement by refusing to accept liability for deposits exceeding \$100,000, nor did they provide financial support for a merger of the bank. For the first time since the creation of the FDIC, large depositors in an insured bank actually suffered losses. Whether this helped to hasten or to forestall later failures of other depositories remains a debatable issue. In any event, when the authorities later were tested by runs on truly giant institutions, namely the Continental Illinois Bank and the savings and loan subsidiary of Financial Corporation of America, they really had no choice but to confirm that *all* deposits in institutions of national significance are *de facto* insured. For Continental Illinois, in addition, the regulators felt obliged also to guarantee, over the public objection of Treasury Secretary Regan, the credit market liabilities of the holding company that owned the bank. Although it was carefully stipulated that no precedent was intended, this allowed another large camel to

slip its nose under the tent. The recent entry of major insurance companies into the business of insuring banks and bond investors against loan defaults represents another effort to stretch the safety net. Now, it can be presumed, the authorities will have to interdict a cascading of defaults if only to save the insurance industry.

Also in 1982, major problems arose in connection with the rescheduling of the debts of Mexico, Brazil, and other foreign countries, default on which would have decimated the capitalization of leading American banks. The Mexican crisis came to a head in the summer, when the U.S. financial system was already in a state of jitters. The Treasury and the Federal Reserve promptly undertook a rescue operation that reassured all concerned not only of the safety of their deposits, but also that the affected banks would not have to abruptly curtail their operations. As a result, the many subsequent foreign debt "crises" have had little if any general market impact.

The cumulative effect of the responses to these and other calamities has been to make the authorities the implicit guarantors of nearly the entire spectrum of widely held debt obligations. This may not be of great concern while inflation remains relatively subdued. Eventually, however, a more pronounced collision is likely between these protective functions and anti-inflation goals. It is difficult to inhibit lending by financial institutions and markets while providing them unconditional shelter.

Mainly as a consequence of the international debt problems, Congress in late 1983 mandated more stringent bank capital regulation. The regulators' response, however reluctant, of closer supervisory scrutiny, public criticism of certain types of merger and

mortgage lending, and promulgation of more formal, and for large banks stiffer capital requirements, appears to be exerting some restraining impact on the growth of credit. This approach implies renewed experimentation with credit-control (crunch-producing) techniques whenever the next period of sharply restrictive monetary policy eventually reaches the pitch at which it threatens business debtors with insolvency and home mortgage debtors with higher monthly payments. At such a time, the limitation of credit growth by means of binding capital-to-asset ratios would skyrocket interest rates. In addition, lenders would further restructure their portfolios so as to minimize holdings of governmental securities, mortgages, and other low-risk, low-return credit. The likely political reaction would be toward more specific regulation of interest rates and portfolio composition.

I have long argued that deregulation of financial markets, particularly as respects deposit interest rates, will ultimately spawn new and broader control machinery more onerous than its forebearers. That federal authorities with an ideological commitment to full financial deregulation find themselves newly immersed in intense "hands-on" supervision is strong evidence that such a trend to reregulation has started.

## MACROECONOMIC ANALYSIS OF LEADING INTERWAR AUTHORITIES†

### Marriner S. Eccles, Chairman of the Federal Reserve Board

By L. DWIGHT ISRAELSEN\*

The inherent instability of capitalism may be corrected by conscious and deliberate use of three compensatory instruments, taxation, varying governmental expenditures, and monetary control.  
*Marriner S. Eccles, 1935*

Yours was the only revolution on record that entered government by way of a central bank.

*John Kenneth Galbraith to  
Eccles, 1976*

On July 29, 1983, the Federal Reserve Building in Washington, D.C. was formally named in honor of Marriner S. Eccles, who served as Governor of the Fed, 1934–36, as Chairman of the Board of Governors, 1936–48, and as member of the Board, 1948–51. While Eccles was honored primarily for his struggle to maintain Federal Reserve independence to conduct monetary policy, his role in introducing “compensatory” monetary and fiscal policies—modern macroeconomic stabilization policies—was undoubtedly of equal importance. In tracing the development of Eccles’ macroeconomic philosophy, this study identifies him as one

of the earliest American precursors to Keynes, and as the most important figure in the introduction of “Keynesian” economic policies in the United States.

#### I. Changing Views

We must acknowledge that progress comes only through toil, economy and thrift, and that these alone are the motive power which creates the enduring structure.  
*Eccles, 1925*

The matter of economy is negative, the matter of spending is positive, and we have been doing the negative thing rather than the positive. We have been preaching the negative doctrine.... Our depression was not brought about as a result of extravagance.... The difficulty is that we were not sufficiently extravagant as a nation. We did not consume what we were able to produce.  
*Eccles, 1932*

In February, 1933, the Finance Committee of the United States heard testimony on the causes and cures of the depression. While farmers argued for remonetization of silver as a means of recovery, and labor spokesmen suggested reduced hours and work weeks, the majority of the 46 prominent Americans who testified were of the opinion that the depression represented the workings of natural economic law, a punishment for the “extravagance” of the 1920’s, and that to interfere with the cycle of boom and bust was to invite disaster. Balancing the federal budget in order to “restore confidence” was seen as the only prudent course open to government, a policy reflected in the 1932 political campaign, in which both major parties advocated a balanced budget as the key to economic recovery. In an effort to reduce the deficit,

†*Discussants:* Raymond W. Goldsmith, Yale University; Takafusa Nakamura, University of Tokyo.

\*Associate Professor of Economics, Utah State University, Logan, UT 84321. I am indebted to personnel at the Special Collections Library, University of Utah, for assistance in working with Eccles’ papers, the Marriner S. Eccles Collection (hereafter *MSE*). I also benefited greatly from conversation and correspondence with economists acquainted with Eccles and his work, particularly Lauchlin Currie, Evsey D. Domar, Milton Friedman, John Kenneth Galbraith, Charles P. Kindleberger, Richard A. Musgrave, and Herbert Stein, none of whom should be held responsible for my inferences and conclusions.

Congress had passed in 1932 what was to that point the largest tax increase in U.S. history. Toward the end of the hearing, Eccles was called to testify. Eccles, 43-years-old, was a successful Utah banker and industrialist, a "conservative Republican" whose formal schooling had ended after three years of high school, but whose business acumen had enabled him to bring his commercial and banking interests through the worst years of the depression relatively unscathed.

In his testimony, Eccles identified the cause of the depression as an insufficiency of effective demand, rather than punishment for past extravagances, loss of confidence, or workings of natural law. The cure, Eccles stated, was a restoration of sufficient spending to purchase the quantity of goods which it was possible to produce at full employment. Because the profit motive could be expected to lead individuals, business, and financial institutions to make decisions which would further reduce spending, hence income and employment, the government, motivated not by profits, but by the welfare of the public, must compensate by spending more. "I see no way of correcting this situation except through Government action," Eccles declared (*MSE*, Senate Finance Committee, *Investigations of Economic Problems*, "Statement of M. S. Eccles, President First Security Corporation, Ogden, Utah," February 24, 1933, p. 712). He then proceeded to outline a five-point program of unemployment relief, public works, agricultural allotment, farm mortgage refinancing, and permanent settlement of interallied debts to deal with the immediate problems of the depression. He also proposed a plan for long-run economic stability that included unification of the banking system under the Federal Reserve and the creation of an agency to guarantee bank deposits; tax reform to achieve a more equitable distribution of wealth and purchasing power; passage of national child labor, minimum wage, unemployment insurance, and old-age pension laws; federal agencies to approve all new capital issues offered to the public and all foreign financing, all means of transportation, and all means of communication to insure their operation in the public interest; and a national planning board to coordinate public and private economic ac-

tivities (see also pp. 712-33). Eccles' testimony was received by the Finance Committee with a mixture of interest, skepticism, disbelief, and outright hostility. Three years later, a cover story in *Time Magazine* evaluated his 1933 proposals in the following terms: "Eccles laid before a Senate committee a plan, which turned out to be nothing less than a detailed blueprint of the New Deal. Only one Eccles suggestion has not materialized—official cancellation of War Debts" (February 10, 1936, p. 60).

Marriner Stoddard Eccles was the eldest son of the second wife of David Eccles, Utah's first native millionaire. David Eccles, who had been illiterate when he emigrated from Scotland to Utah at the age of fourteen, left an estate appraised at more than \$7 million when he died in 1912 (see Leonard Arrington, 1975). Marriner Eccles' success in consolidating and managing his father's estate has been documented in Eccles' autobiography, edited by Sidney Hyman (1951).

In addition to wealth, Eccles inherited from his father a set of beliefs about the proper roles of individuals and government in the functioning of the economic system. In the automatically functioning, self-adjusting, capitalist economy, the role of government should be limited to "maintaining confidence" through strict budget-balancing, while the greatest benefit would be received by those individuals who worked hard, practiced strict economy, and invested prudently (Hyman, 1951, pp. 4-5, 21, 37, 51). "We must acknowledge," Eccles told Utah bankers in 1925, "that progress comes only through toil, economy and thrift, and that these alone are the motive power which creates the enduring structure" (*MSE*, written address, June 1925, p. 3). As the crash of 1929 deepened into prolonged depression, Eccles was forced to reevaluate his thinking. Early in 1931, he recalls, "I saw for the first time that though I'd been active in the world of finance and production for seventeen years and knew its techniques, I knew less than nothing about its economic and social effects. The discovery of my ignorance, however, did not by itself lead anywhere.... As an individual I felt myself helpless to do anything" (Hyman 1951, pp. 54-55). Eccles had run aground on the shoals of macroeconomics.

The reformulation of his thinking was reflected in his public addresses. In a speech to bankers in the spring of 1931, Eccles said, "The modern system by which society supplies its wants...is a wonderfully effective organization when in balance..., but if anything happens to throw it out of balance it is possible to have millions of people unable to buy the products of others because they cannot sell their own" (*MSE*, written address, March 26, 1931, pp. 5-6). Eccles had by this point rejected the idea of the automatic restoration of economic prosperity through the workings of the invisible hand of narrow self-interest. He had discovered the fallacy of composition, and had concluded that "intelligent and courageous" open-market purchases by the Fed could have averted the drastic deflation which followed the crash. He had also concluded that underconsumption, not overproduction, was the basic cause of the depression (see also pp. 4-5, 7-8).

During the period 1931-33, Eccles developed and expanded the underconsumption theory, and by 1933 had arrived at the essential framework of Keynesian analysis and policy. The evolution in his thinking can be identified in his public addresses of 1932 and 1933. In a 1932 speech, Eccles declared, "Our depression was not brought about as a result of extravagance.... The difficulty is that we were not sufficiently extravagant as a nation. We did not consume what we were able to produce" (*MSE*, written address, June 17, 1932, pp. 2-3). Eccles mentioned the fallacy of composition problem and the futility and perversity of government efforts to balance the budget, which could only lead to further unemployment. "Just to the extent that unemployment increases," said Eccles, "just to that extent are you going to find it more impossible to...balance any budget" (p. 4). Popular theories of causes of the depression were dismissed: "These are not acts of God, they are mistakes of man" (p. 6). Traditional theories of economic recovery were also discarded. "The theory of hard work and thrift as a means of pulling us out is unsound economically. True hard work means more production, but thrift and economy mean less consumption.... Now for the solution to our problem," said Eccles, "How are you going to put these people back to

work? There is only one agency in my opinion that can turn the cycle upward and that is the Government. ...[T]he Government, if it is worthy of the support...of its citizens, must so regulate, through its power of taxation, through its power over the control of money and credit,...the economic structure so as to give men...the opportunity to work" (see pp. 5-6).

Eccles had further refined his ideas by 1933. On economic recovery through spontaneous revival of investment, he said, "The assumption of spontaneous revival through new investment has always rested on the fallacious belief that people and banks will not indefinitely hold money in idleness" (*MSE*, written address, October 27, 1933, p. 3). On the notion that a shortage of currency in circulation was prolonging the depression, Eccles stated, "There is no shortage of currency in circulation.... The need is not for more money, but for more spending" (see pp. 5, 2). To the view that recovery was dependent on the establishment of "sound money," Eccles commented,

For the past two years or more we have had the painfully sound dollar measured by its purchasing power in terms of goods and services. The sounder it got the further prices fell and the more unemployment increased. Had the policy of economy and budget balancing on the part of the Government continued, it would have soon been so sound that all of our credit institutions would have been closed, there would have been no bank money and all of the people would have been starving to death with an abundance of everything for everybody, or at least the willingness and power to produce it.

[See pp. 10-11]

Self-interest cannot be relied upon to create recovery, Eccles told the Finance Committee, since "if we leave our 'rugged individual' to follow his own interest under these conditions he does precisely the wrong thing" (*MSE*, Senate Finance Committee, *Investigations*, February 24, 1933, p. 719). The decline in spending and investment since 1929 "could have been prevented by action of the Government which is the only agency which could continue spending money without re-

gard for profit.... Financial fuel is piled up—The Government, and not the bankers, must apply the torch. Motives of public welfare must lead us out of the present depression as greed and war have led the world out of past depressions,” Eccles said (*MSE*, written address, October 27, 1933, pp. 2, 4).

## II. Compensatory Economics

The government must be looked upon as a compensatory agency in this economy to do just the opposite of what private business and individuals do. The latter are necessarily motivated by the desire for profit. The former must be motivated by social obligation.

*Eccles, 1936*

By the mid-1930's, Eccles' compensatory policy recommendations were based on a sophisticated macroeconomic analysis which covered the consumption function; the multiplier; a distinction between the relative sizes of the government expenditure and transfer-tax multipliers; leakages and injections; causes of inflation; liquidity trap; velocity; the transmission mechanism of monetary influences; the Phillips curve relationship; the relationships among wage increases, productivity increases, and inflation; the role of inflationary and deflationary expectations; income and wealth distribution effects; the coordination of monetary, fiscal, and incomes policies; and the interrelationships between domestic stabilization policies and international movements of goods and capital. While he was not interested in the construction of a formal model, all of the elements of Keynesian analysis, with the possible exception of the accelerator, may be found in his speeches, letters, and memos.

All policies which came under Eccles' scrutiny were examined for stabilization implications. As an example, Eccles felt that Social Security taxation should be deliberately controlled in a countercyclical fashion, with increases in rates during booms and reductions during depressions. Taxation in general should be used mainly as a means of redistributing income from wealthy individuals and corporations to low- and middle-class

consumers who had, Eccles believed, higher marginal propensities to consume. He said in 1933,

The fundamental economic plans, when they are finally established, will of necessity center in the distribution of purchasing power and in the allocation of income between investment and expenditure.... They will involve relief of taxation that rests on the consumer... [and] the establishment of heavy income taxes especially in upper brackets. They will involve heavy taxation of undistributed corporate surplus, to force corporate income into dividends and taxes. [p. 7]

A good summary statement on compensatory policy was delivered by Eccles in 1935, when he declared his hope that “the inherent instability of capitalism may be corrected by conscious and deliberate use of three compensatory instruments, taxation, varying governmental expenditures, and monetary control.... It should be evident by now,” he said, “that simple maxims and rules of thumb are not sufficient” (*MSE*, written address, February 16, 1935, pp. 21–22).

Eccles saw in the instability of capitalism the seeds of destruction; in compensatory policy he saw the mechanism of salvation.

If we regard capitalism simply as a particular economic organization of society, our defense of, or attack on, that organization must be directed toward its effectiveness—its ability to satisfy in an adequate and equitable fashion the material needs of mankind. If it cannot be defended on these grounds it is doomed.... Private enterprise today is on trial solely because it is not producing the goods it has the capacity to produce and because it is not providing a more equitable distribution of the goods it is producing. [pp. 2–3]

The major threat to capitalism, Eccles believed, lay in the creation of a large group of unemployed. “These people no longer have any stake in preserving our present economy. They have nothing to lose. And if this condi-

tion persists...neither you nor I will have anything to lose" (pp. 2-3). "You have got to take care of the unemployed," he told the Finance Committee, "or you are going to have a revolution in this country" (*MSE*, Finance Committee, February 24, 1933, p. 733).

### III. Influences

My own viewpoint has sometimes been erroneously identified with that of Mr. Keynes, doubtless to his embarrassment. *Eccles, 1939*

I know of no professors whose writings have influenced me. *Eccles, 1949*

Eccles' contention that he arrived at his economic philosophy without having read Keynes (see Hyman, 1951, pp. 131-32) is accepted by his biographers (see Hyman, 1976, p. 128; Dean May, 1981, pp. 53, 58-59; Herbert Stein, 1969, p. 148). He had, in fact, read *something* by Keynes, as he quoted Keynes in 1933 on the difficulty of gaining public acceptance of deficit spending except in wartime (*MSE*, written address, October 27, 1933, p. 8). By this time, however, Eccles' ideas were already well-formulated, and he was actively searching for evidence and confirmation, such as he had found in the writings of Foster and Catchings (Hyman, 1976, pp. 93-94). With this minor exception, Eccles had apparently read nothing by Keynes before he came to Washington as Assistant to Treasury Secretary Morgenthau in 1934. His later exposure to Keynes' works was also limited. As Lauchlin Currie, Eccles' first and most important economic advisor recalls, "[Eccles] never read Keynes' *General Theory*, and he accepted the Keynesian arguments, when I summarized them [in a written review prepared for Eccles in November 1936], as a matter of course. Nothing new!" (Currie to author, letter, August 24, 1983). Eccles claimed to be innocent of any academic influences. "I know of no professors whose writings have influenced me," he stated in 1949 (*MSE*, Eccles to William Merrill, letter, September 22, 1949). The use of the word "professors" is instructive, as Eccles went on to identify eight individuals with whom he

worked at the Fed who might "have possibly had some influence on my thinking." Among those were some, Lauchlin Currie, Alvin Hansen, and Richard Musgrave, who had been and/or would be "professors." Musgrave contends that "economists undoubtedly influenced [Eccles'] thinking,..." His discussion of public debt in particular strongly reflects Hansen's position" (Musgrave to author, letter, September 22, 1983). These influences apparently came through the working relationship, rather than through "academic" writings. Evsey Domar recalls that Eccles never came to the Federal Reserve Seminar, which was established during the war with Keynes being the first speaker. "Somehow," Domar writes, "I have the impression that he did not care much for academic economists" (Domar to author, letter, July 6, 1983). Likewise, states Milton Friedman, "the academic world was not influenced by Eccles" (Friedman to author, letter, July 22, 1983). The academic world, however, was very much aware of Eccles' analysis and policy, as is indicated by his correspondence with many prominent economists. Irving Fisher, then Professor Emeritus at Yale, was one with whom Eccles had correspondence on several occasions. Although Fisher had written a very favorable three-part essay on Eccles' views in 1935 (*MSE*, Irving Fisher, "The Mind of Mr. Eccles," 1935, ms.), Eccles did not always agree with Fisher's views. In 1938, for example, Eccles, in a draft reply for Franklin Delano Roosevelt's signature, pointed out the flaws in a plan strongly urged on the president by Fisher to bring about economic recovery by monetizing the float. In submitting the draft, Eccles commented on such plans pressed on the president, and concluded, "I am returning also, with a suggested reply as you requested, the correspondence from Professor Irving Fisher, who is much more intelligent but certainly misled on this point" (*MSE*, Eccles to M. H. McIntyre, letter, June 2, 1938). "If he felt he was right," recalls Currie, "he was not in the slightest impressed by 'authority' to the contrary" (Currie to author, letter, August 24, 1983). This characteristic was evident in his belief, contrary to the opinions and advice of

his economists, that the war would be followed by inflation, not deflation.

Quite aside from any influences from economists to which Eccles might have been subjected during the early 1930's or later, the fact remains that he came to a view of the workings of the macroeconomy which was practically unthinkable for one from his background. Eccles attributed the advanced nature of his thinking to the fact that he was a country banker and had not attended college (Stein, p. 485, fn. 47). Currie's explanation is to suggest that "he was what in biology is called a mutation!" (Currie to author, letter, August 24, 1983). Perhaps Eccles' Mormon background preconditioned him to see a role for government in economic planning and a stabilization. Mormon economic policy during the nineteenth century was characterized by strong central direction and control, and Mormon economic institutions blended principles of self-reliance and cooperation.

Whatever the explanation for the evolution of Eccles' ideas on macroeconomic policy, his was a remarkable intellectual accomplishment, and one which has had lasting impact. Musgrave, Eccles' personal assistant from 1944 to 1948, considers Eccles as "a great figure in a crucial period of our history... an extraordinary figure, with a great deal of insight and courage. ...It is easy," writes Musgrave, "to belittle theoretical qualities in a man of action such as Eccles; yet which academic, other than Keynes, was as important in implementing a modern view of macro policy into actual policy measures?" (Musgrave to author, letter, September 22, 1983). Friedman does not exempt even Keynes from the assessment when he states,

"I believe [Eccles] played a far greater role in the development of what came later to be called Keynesian policies than did Keynes or any of his disciples" (Friedman to author, letter, July 22, 1983).

Eccles was a paradox: a developer of economic theories who expressed an intense dislike of "theory" and categorically denied being an economist; a "conservative Republican businessman-banker" who served a Democratic president and delighted in pointing out logical flaws and backwardness in the thinking of bankers and businessmen; and a defender of the free-enterprise market economy who believed that only significant government intervention in the economy could save the system.

# Rudolf Hilferding: The Dominion of Capitalism and the Dominion of Gold

By WILLIAM A. DARITY, JR. AND BOBBIE L. HORN\*

In November 1918, the USPD-SDP provisional revolutionary government established a commission to study the socialization of German industry. Its members included Karl Kautsky, Emil Lederer, and, of all people, Joseph Schumpeter. Later when asked how he could have been connected with such a commission, Schumpeter reportedly replied that if somebody wants to commit suicide, it is a good thing if a doctor is present. Weimar Germany had its "doctor," a trained physician, also a member of the socialization commission, in Rudolf Hilferding. As the economic expert of the SDP and twice Finance Minister in coalition governments, Hilferding sought to prescribe treatments as German socialism's humanitarian midwife.

Hilferding's name probably is most familiar to economists for his early skirmish with the dreaded Böhm-Bawerk over the equally dreaded transformation problem and for the qualified recognition of his treatise *Finance Capital* in Lenin's *Imperialism*. A number of factors should stimulate a renewed interest in this early theoretician of corporate capitalism. First, the recent publication of an English translation of *Finance Capital* (1981) means fewer will be limited to accepting authoritative summaries without some perusal of its contents. Second, there is a continuing and important interest in Marx's theory of money. Third, finance and financial crises persist in intriguing economists and still await satisfactory treatment. Combined with the receding tides of Keynesianism and Monetarism, and the resurgence of "Classicals" of all colors, it may prove interesting to reconsider Hilferding's efforts.

In this paper, we address three issues. First, we look at Hilferding's career and his contributions to Austro-Marxist doctrine. Second, we consider his two experiences as Finance Minister: 1) facing the crisis of the infamous German hyperinflation; 2) pursuing deflationary policies on the eve of the Great Depression. Last, we offer some very brief comments on the relationship between his political activities and his intellectual work as a socialist theoretician.

## I. Austro-Marxism

Born into what Paul Sweezy described as a "well-do-do Jewish mercantile family" (1949, p. xv) in Austria in 1877, Hilferding trained in medicine at the University of Vienna, receiving his doctorate in 1901. While at the university he became actively involved in the socialist movement and was drawn to the study of political economy. His contact with the central figures of the "Austrian school" laid the foundation for his Marxist critique of subjectivist approaches in economics.

Hilferding soon became a leading figure in the Austro-Marxist school. In 1904 with Max Adler, he inaugurated the *Marx-Studien*, the theoretical organ of the Austro-Marxists. In 1906 he was lecturing at the Workers University at Berlin, along with Rosa Luxemburg. He subsequently edited *Vorwärts*, a major socialist newspaper and in 1910 published his major work *Finance Capital: A Study of the Latest Phase of Capitalist Development*. After the war he edited *Freiheit*, the journal of the Independent German Social Democratic Party (USPD) and upon the fragmentation of the USPD moved with other right wing independents to the German Social Democratic Party (SDP). He obtained German citizenship in 1920 and served as Weimar's Minister of Finance briefly in 1923 and again, for a somewhat more extended

\*University of North Carolina, Chapel Hill, NC 27514, and University of Tulsa, Tulsa, OK 74104. We thank Steve Steib, Cadwell Ray, and Charles Kindleberger for comments.

period, in 1928–29. While not holding a cabinet post, Hilferding served as a member of the Reichstag and edited the SDP's theoretical monthly, *Die Gesellschaft*. With the victory of the National Socialists—a possibility denied by Hilferding only a few days before Hitler's appointment to the Chancellorship—he was compelled to flee into exile and forced to redirect his attention from the Communist threat to the harder reality of the National Socialists. Eventually turned over to the Gestapo by the French authorities in 1941, he reportedly hung himself in his jail cell.

Hilferding is considered the leading economic theoretician of Austro-Marxism, a movement that is of special importance to economists because of a common historical and intellectual environment shared with the Austrian school of economics. Both Austro-Marxism and Austrian economics reflected similar influences and demonstrated mutual awareness of their respective approaches. Hilferding displayed sensitivity to the Austrian tradition (along with the German monetary tradition) in the pages of *Finance Capital* and felt obliged to defend Marx from critiques launched from such perspectives. Both Hilferding's Austro-Marxist economics and that of the Austrian school placed special emphasis on distortions in the structure of prices as fundamental to the propagation of capitalist crises. Hilferding's interesting attitude toward the price system is apparent in his last publication (1963). However, for the Austrians the source of these distortions was autonomous to the market process, coming particularly from the state. In contrast, for Hilferding these distortions had an endogenous origin in the normal workings of a capitalist economy, even under thoroughgoing *laissez-faire*, though the state could be one source.

Hilferding's Austro-Marxist economics produced two related theories of capitalist crises. The primary theory was his conversion of Marx's "law of the tendency of the rate of profit to fall" into simply a statement about the capitalist business cycle. Hilferding, in rejecting what he termed "the dogma of the falling interest rate" (1981, p. 104), shifted to a treatment where the rate of profit

is something that swings periodically rather than secularly downward. Thus, he moved away from Marx's conceptual interpretation of the rate of profit in pure form. This move from Marx's original approach may have been due to Hilferding's inclination to view Marx's work as the culmination of classical political economy rather than the most substantive critique advanced to that date (Henryk Grossman, 1977, p. 48). For better or worse, Hilferding's Austro-Marxist economics was a variant of Marxism, without immunity to influences from Austrian economics or other "modern" movements—an idiosyncratic species of Marxism indeed!

While Hilferding viewed capitalism as historically doomed, he did not (as did Marx) attribute its demise directly to the tension between the progressive reduction of socially necessary labor time and the fact that labor power constituted the sole source of profit. Hilferding foresaw a transformation of the economy with growing centralization and concentration of capital as the normal outcome of competition under capitalism.

Hilferding's second major explanation for capitalist crises, in addition to cyclical swings in the rate of profit, was the classic Volume II problem of disproportionality in production. The failure of the capitalist pricing mechanism to produce the appropriate signals would lead to imbalances in the production of goods across the various sectors—especially between wage goods and capital goods. In fact Hilferding even suggested that the cyclical drop in the rate of profit would go hand in hand with "the disruption of these proportional relations." (For a complete discussion, see pp. 239–66.)

In exploring the crystallization of crisis, Hilferding identified three primary factors in the recurrent fall in the profit rate: 1) the extension of turnover time, 2) the rise in the wage rate associated with the growth in demand during the upturn of the cycle, and 3) the rise in the rate of interest above normal levels adversely affecting entrepreneurial profit. However, somewhat strangely, the crisis appeared to lack inevitability: "A monetary crisis is not an absolutely necessary feature of the crisis, and may not always occur" (p. 274). Banks could avert the crisis

if they would continue to make credit available to producers. But the private banks could, not or would not, make funds available for two major reasons, according to Hilferding:

In the first place, speculation in both commodities and securities is in full spate and makes increasing demands on the supply of credit. Second,..., the circulation credit which producers extend to each other becomes inadequate to meet the increased demands, and here too the banks must help out.

[p. 260]

The banks would do their utmost to keep their retained profits "in liquid form, as money"; therefore the conversion into "productive capital," that brings high employment and continued prosperity, does not take place. A Hilferding crisis of economic depression, although finding its origins outside of the specific characteristics of the financial apparatus, is often confirmed by the withdrawal of credit. It is in keeping with Hilferding's position, as the economic theoretician of the Austro-Marxist school, to construct such a vision of capitalism—unstable, volatile, prone to crises—the antithesis of the vision of Austrian economics, yet sharing many of the same views about the mechanisms of the capitalist economic system.

## II. The Socialist Finance Minister

Hilferding's brief first tenure as Finance Minister began in August 1923, at the height of the hyperinflation, when Gustav Stresemann was called upon to form a coalition government. Hilferding clearly inherited a situation which called for immediate and radical action. Hilferding had the opportunity to adopt Lenin's dictum (as reported by Keynes, 1963, p. 77) and attempt to "destroy the Capitalist System" by debauching the currency. But Hilferding did not want to destroy capitalism; he was not looking for an economic collapse, but rather "a collapse which will be political and social..." (1981, p. 366), amounting to a social and political transformation of the capitalist economy. For Hilferding, the pressing problem was that of

domestic inflation. Renegotiation on reparations, and almost all else, required monetary stabilization as a precondition.

It is difficult, if not impossible, to gauge the nature and extent of the gulf between the theory of *Finance Capital* and Hilferding's policies as Finance Minister. One would assume that Part I of *Finance Capital*, "Money and Credit," would be relevant to his political practice, particularly in an era of hyperinflation. For some of his critics, it was relevant; that was one of Hilferding's problems.

Part I is probably the most controversial portion of the book. It was about this section that Lenin expressed the reservation that *Finance Capital* "gives a valuable theoretical analysis" despite an unspecified "mistake the author commits on the theory of money" (p. 11). Even Hilferding's theoretical ally Kautsky (see Harold James, 1981, p. 852) voiced disagreement, and Schumpeter dismissed it as "rather old-fashioned monetary theory" (1954, p. 881). So too with modern commentators: The editor of the new English translation describes it as "[p]erhaps the least successful part of the book" (p. 5); reviewer Anthony Brewer (1983, p. 102) suggests skipping the section; and David Harvey (1982, pp. 290–92), following de Brunhoff, situates many of Hilferding's errors in his misreading of Marx on money.

One of the primary tasks in Hilferding's (1981) treatment of money is to offer an explanation of the determination of the value of a pure, nonredeemable, state paper money; an explanation of the "modern monetary experience" of Holland, Austria, and India.

Hilferding's monetary doctrines do not rest comfortably in any of the standard monetary camps. He accepts that "ever since Tooke's demonstration, the quantity theory of money has been rightly regarded as untenable" (p. 47); however, "there is a reluctance to give due recognition to the influence of quantity on the value of money even where it really is the determining factor, as in the case of paper money and depreciated currency" (p. 50).

From Hilferding's perspective, the theoreticians of the Cuno government, the Knapp-Helfferich school, simply went too far in their rejection of the quantity theory and

were stymied by their value theory from devising a theoretically satisfactory explanation. For Hilferding, "The quantity theory, then, holds good for a currency with suspended coinage. After all, the theory was formulated as a generalization of the experience with unsettled currencies at the end of the eighteenth century in America, France and England" (p. 55).

He gives a number of reasons for the impossibility of a pure paper currency system. "A pure paper currency is, therefore, impossible as a permanent institution, because it would subject circulation to constant disturbances" (p. 57). However he lays out a system in the "abstract" in which the quantity of "legal tender state paper money" could not be increased, and "[t]he impossibility of increasing the supply of paper money would protect it against depreciation" (p. 57), while banks could provide an endogenous credit money component to prevent appreciation. "Under such circumstances, paper money would behave as gold does today..." However, "reality" throws up three obstacles to such a scheme:

In the first place, this paper money would be valid only within the boundaries of a single state. For settlement of international balances, metallic money with an intrinsic value would be required; and if this requirement is to be satisfied, the value of the money in domestic circulation must be kept on a par with the medium of international payments to avoid the disruption of commercial relations. [pp. 57-58]

Second, "there is no possible guarantee that the state will not increase the issue of paper money." He ends with a third reason: "money with an intrinsic value—such as gold—is always needed as a means of storing wealth in a form in which it is always available for use." For Hilferding, explanation of Germany's inflation was straightforward.

Hilferding's analysis would require linking of the mark to gold, primarily to constrain the state's financial activities. But also, for him capitalism maintains a certain infatuation:

Credit collapses, and thus suddenly deserted capitalism returns in despair to its first love, to gold.... Capitalism thought that it had long since liberated itself from the domination of gold, but now it experiences a bitter disillusionment, and shaken by panic reorganizes its continuing dependence. But such crises are cathartic.... Nevertheless, the more capitalism succeeded in establishing its own domination, the less did it allow itself to be bound by this golden chain. The loved one, once so demanding, learns to be more modest and is eventually satisfied with the role of someone in reserve.... Her demands may become excessive, and she may occasionally refuse her favors altogether, but these moods do not last long and things soon return to normal. Gold has lost, once and for all, its absolute domination.... [p. 274]

He saw that even the authority of the state was limited ultimately under the laws (and loves) capitalism. In October of 1923, Keynes was writing:

A regulated non-metallic standard has slipped in unnoticed. *It exists*. Whilst the economists dozed, the academic dream of a hundred years, doffing its cap and gown, clad in paper rags, has crept into the real world by means of the bad fairies—always so much more potent than the good—the wicked Ministers of Finance. [pp. 208-09]

The Minister Hilferding, perhaps not sufficiently wicked, accepted limits on the powers of even the bad fairies.

To most interests, any return to gold appeared strongly deflationary in the context of the German situation. But in Hilferding's theory it was not necessarily the case. For with a stable money, the banking system could create a sufficient quantity of domestic credit money to maintain the "social minimum of circulation." But, moreover, in spite of any deflationary implications, there appeared no alternative.

Opponents to the return to gold possessed as one alternative, Helfferich's "ryemark/

rentenmark" scheme, which appeared to avoid the deflationary implications of returning to gold while instilling public confidence in a new currency; partly a scheme, partly a bluff (see Erich Eyck, 1963).

Hilferding's role in the ultimate action is unclear. He served as Finance Minister from mid-August to the end of September, and the currency reform was introduced in mid-October after Hilferding had been forced to resign. The ultimate plan adopted was a hybrid of the two proposals with a Rentenbank being established, issuing notes backed by mortgages with the value not tied to rye, but instead to gold. The other crucial aspect was a restriction on the Reich in terms of discounting its bills with the Reichsbank.

Hilferding returned to the post of Finance Minister in June of 1928 in the coalition government of Hermann Muller. This year marked the last of the "golden years" with unemployment of 7 percent, just before the massive collapse driving unemployment beyond 30 percent by 1932. Hilferding remained in office until December 1929 when he resigned in a controversy surrounding the negotiations of a state loan with an American banking concern. The primary concern of Hilferding in this period was the control of the budget and arrangements to "fund," as opposed to monetize, that portion that could not be covered by taxes. The deficits from the budgets of 1926 and 1927 had created funding problems and the unemployment insurance credits were rapidly mounting. Hilferding proposed both budget reductions and tax increases, policies that met with wide opposition, all the while resisting "inflationist" schemes.

So, though not necessarily a "hard-money" man, Hilferding was a "sound-money" one. His position seems remarkably close to that of an individual who politically could not be more different, an American contemporary, J. Lawrence Laughlin, who also thought of himself as a monetary doctor of sorts. Both rejected the quantity theory, except for the case of inconvertible state paper money; and, moreover, both rejected the viability of such an institution as a permanent arrangement. Both accepted some form of the so-called "real bills" doctrine and possessed some form

of "objective" value theory. Theoretical consistency and policy construction often produces peculiar bedfellows.

### III. Theory and Practice

Given Hilferding's notion of the increasing concentration and centralization of finance capital, an idea that ultimately matured into his concept of "organized capitalism," he seems to have thought that it would be better to simply let the system evolve, according to its own inherent logic. Let the system develop organizational forms and mechanisms to cope with the surface manifestations of the underlying contradictions, and then simply take it over, by democratic means, with its essentially "socialistic" organizational structure already in place.

Analysis of Hilferding's theoretical stance is both complemented and complicated by the fact that his political activity seems to have offered the opportunity to test his theory. It is a widely held view, particularly on the left, that, to quote Sweezy: "his record, like that of the Social Democratic Party itself, was one of unbroken failure. As Finance Minister he was equally ineffective in dealing with inflation in 1923 and with impending depression in 1929" (pp. xvii-xviii).

Gerd Hardach et al. echo this view and write that Hilferding "made drastic mistakes on virtually every relevant economic question of the time: on structural unemployment in the 1920s, on the outbreak of the world crisis and finally on stabilization policy" (1978, p. 56). These authors attribute these "drastic mistakes" to Hilferding's "...complete reformism. Marxist theory was...only a rhetorical reference point—for concrete analysis social democracy relied on bourgeois economics" (p. 56).

Hilferding seemed to view Marxian political economy as having an almost positivistic scientific autonomy.

...[S]o far as Marxism is concerned the sole aim of any inquiry—even into matters of policy—is the discovery of causal relationships.... According to the Marxist conception, the explanation of how such class decisions are

determined is the task of a scientific, that is to say a causal, analysis of policy. The practice of Marxism, as well as its theory, is free from value judgements.

[p. 23]

This view of Marx and this separation of Marxist political economy from some inherent working class perspective can be sensed from Schumpeter's evaluation of Hilferding's as Finance Minister:

The minister Hilferding, much too good an economist not to see what was wrong and much too good a Marxist not to realize that there are situations in which anticapitalist policy is in the end anti-socialist, actually went so far as to attempt a very 'capitalistic' fiscal reform. [1939, p. 715]

# Korekiyo Takahashi and Japan's Recovery from the Great Depression

By DICK K. NANTO AND SHINJI TAKAGI\*

The economic policies of Japan's Finance Minister, Korekiyo Takahashi, during the Great Depression are more than a curious footnote in economic history. By 1932, Takahashi's interventionist policies had reversed Japan's economic decline. They also preceded similar measures adopted in other countries. Takahashi has even been characterized as Japan's Keynes, because of his use of deficit-financed, fiscal stimuli. He also has been blamed for his role in initiating in Japan the process of expanding military expenditures to stimulate the economy.

This paper takes a second look at the Japanese economy during the early years of the Great Depression, with a particular reference to the policies of Takahashi. Two major questions addressed relate to the Keynesian origin of his ideas and the extent to which his policies contributed to the subsequent economic recovery.

## I. Economic Background

In real terms, the Great Depression scarcely occurred in Japan. From 1926 through the 1930's, real gross national product (*GNP*) in each succeeding year never declined from its previous level. The economy did experience some stagnation in the 1929–31 period; real *GNP* rose by only 0.5 percent in 1929, 1.1 percent in 1930, and 0.4 percent in 1931. For the remainder of the 1930's, however, real *GNP* grew at an average annual rate of 5.8 percent.

Real gross domestic product (*GDP*) by sector, however, did decline from peak to

trough during the 1928–33 period; it fell by 7 percent overall, 12 percent for agriculture, 7 percent for construction, 6 percent for transportation and communications, and 25 percent for commerce and services. For manufacturing and mining, however, real gross domestic production rose in each year of the Great Depression except for 1932, when it dropped by 1 percent.

What did occur during this time were severe upheavals in Japan's monetary and fiscal systems in concert with worsening economic conditions abroad. This caused overall stagnation, declines in production in some sectors, a severe deflation, and rapid losses in Japan's gold reserves. This was compounded by major crop failures and sharp reversals in monetary and fiscal policies.

Declines in nominal *GNP* levels defined the dimensions of the depression for most producers. The *GNP* dropped by 1 percent in 1929, 10 percent in 1930, and 9 percent in 1931, before beginning to recover. The declines were caused, however, mostly by a drop in prices and not in production.

In Japan, the episode of the Great Depression was preceded by a decade of general economic stagnation following the wartime boom of 1914–18 and was precipitated by a series of political and economic events that began with the financial panic of 1927.

In 1927, following the closing of the Bank of Taiwan, bank runs swept the nation. By the time a three-week moratorium was declared, as many as 27 banks had suspended operations. The Bank of Japan came to the rescue by opening its discount window and nearly tripling its loans in one month. As the crisis ended, banks were awash in liquidity but reluctant to make risky loans.

As the economy continued to perform sluggishly, pressures began to build to return to the gold standard. Bankers wanted to be able to invest their excess liquidity overseas,

\*Congressional Research Service, Library of Congress, Washington, D.C. 20540, and International Monetary Fund, Washington, D.C. 20431, respectively. Views expressed do not necessarily reflect those of the International Monetary Fund.

while the Ministry of Finance was facing the need to refinance 230 million yen in government bonds held abroad (Kozo Yamamura, 1972, p. 195).

Under these circumstances, the Kenseikai party formed a new cabinet in July 1929 with its Finance Minister, fiscally conservative Junnosuke Inoue, who had long advocated returning to the gold standard. On January 11, 1930, just three months after the Great Crash on Wall Street, Japan went back to the gold standard at the higher pre-World War I parity for the yen.

In retrospect, there could not have been a worse time to return to the gold standard. Japan was hit by a modern-day gold rush never thought possible by the Kenseikai. In 1930, 309 million yen in gold left Japan, and the money supply fell by 13 percent. Prices dropped by 10 percent, causing the real money supply to fall by 2.5 percent, and production in certain sectors to decline. Compounding these problems was a fall in foreign demand for Japanese exports of silk and cotton.

Despite these worsening economic developments at home and abroad, the government and financial leaders still favored the gold standard as late as mid-1931. Attitudes began to change, however, with the collapse of the European financial market in July, a deteriorating military situation precipitated by the Manchurian Incident in September, and the abandonment of the gold standard by England in September.

Under these circumstances and early into the Great Depression, the Seiyukai party regained power and called Takahashi, then 77, back from retirement to serve as Finance Minister for the fifth time.

## II. Korekiyo Takahashi—The Man

Korekiyo Takahashi was born in 1854, the year Commodore Perry sailed his black ships into Tokyo Bay, and died under the weapons of military assassins in 1936; the year that Keynes' *General Theory* was published. Seven times appointed Finance Minister, Takahashi was one of Japan's premier Ministers of Finance and molders of economic policy (Kiyoshi Oshima, 1969).

Adopted into a low-ranking samurai family, Takahashi learned English and in 1867 was sent to the United States for further study. There, contrary to an initial agreement, he ended up as an indentured servant. Rescued from this servitude through the intervention of an American friend, he returned to Japan in 1868 after hearing of the Meiji Restoration.

Takahashi became the first Director of the Patent Office in 1884 and later went to Europe and the United States to study patent law. After a failed silver mining venture in Peru, he joined the Bank of Japan in 1892 where his assignments included selling war bonds in the United States and Europe during 1904–07. In 1911, at the age of 57, he became Governor of the Bank of Japan.

After reaching the top at the Bank of Japan, new horizons beckoned Takahashi. In 1913, he joined the Seiyukai and was soon appointed Finance Minister. Over the next fifteen years, he served in that capacity under four different cabinets, including one of his own. When he was called back to handle the 1927 financial panic, he was already over 70-years-old and in semiretirement. He immediately declared a 21-day moratorium on payments of debts, rode out the panic, and resigned after only 42 days in office.

The 1927 panic, however, was only a harbinger of things to come. In December 1931, as Japan was slipping into the Great Depression, he was appointed Finance Minister for the fifth time and was destined to serve under two more cabinets until his death on February 26, 1936.

## III. Takahashi's Economic Policies

Takahashi lost little time in reversing the contractionary economic policies of the previous cabinet when he resumed office at the end of 1931. The result has been described as "one of the most successful combinations of fiscal, monetary, and foreign exchange rate policies, in an adverse international environment, that the world has ever seen" (Hugh Patrick, 1971, p. 256). The recession that had begun in 1930 was reversed by late 1932, and Japan escaped most of the ravages of the Great Depression.

The essence of Takahashi's economic policies included: 1) the abandonment of the gold standard (December 1931) and export promotion; 2) low interest rates; and 3) deficit spending financed by the sale of bonds through the Bank of Japan (beginning with the fiscal 1932 budget) (Shiro Mori, 1975).

#### A. *The Gold Standard*

The decision to go off gold likely would have been made regardless of who was Finance Minister. Japan probably would not have continued much longer on the standard after England had already abandoned it, after Japan's reserves of gold had dropped in two years from 1,343 million to 557 million yen, and after much of the business community had turned against it.

Still the decision fit into Takahashi's view of the world. He was highly nationalistic and somewhat of a mercantilist. He had opposed the gold standard in the early 1920's and felt Japan's hard-earned gold reserves should be retained—partly to finance colonial activities on the Asian continent and partly as a reserve against future contingencies. He also opposed the attempt to raise the exchange value of the yen.

After the yen's ties to gold were severed, the exchange rate with the dollar depreciated by 50 percent in 1932 and another 50 percent in 1933 before recovering somewhat in 1934. For the four years under Takahashi, the exchange value averaged 4.0 yen as compared with 2.2 yen per dollar for the four years prior to his becoming Finance Minister.

The devaluation of the yen was allowed in order to stimulate exports. As the economy was stimulated, exchange controls were imposed to keep imports from rising too fast. Such exchange controls preceded those adopted by the United States, England, and Germany (Takafusa Nakamura, 1983, p. 233).

The result was a dramatic rise in Japanese exports of goods and services both in nominal and real terms. Nominal exports, which had dropped by 25 percent in 1930 and 16 percent in 1931, rose by 22 percent in 1932 and 25 percent in 1933. In real terms, ex-

ports, which had risen by only 7 percent over the previous two years, jumped by 19 percent in 1932 and 6 percent in 1933. The current account surplus accounted for 38 percent of the rise in real *GNP* over the 1932–33 period.

#### B. *Low Interest Rates*

Takahashi had been a long-time advocate of low interest rates in order to promote business investment and expansion. He had been criticized after World War I for helping inefficient industries through such policies and postponing their needed adjustment. His experience as Governor of the Bank of Japan and close ties to the business community reinforced his adherence to this policy. Low interest rates also were needed to sell government bonds and finance the debt.

Takahashi, furthermore, linked interest rates to income distribution and consumption demand. He thought high rates reduced the share of income going to labor, which reduced the purchasing power of the people, lowered demand, and caused recessions. A low interest rate policy, he argued, was the most effective policy tool to counteract a recession (1936c, p. 235).

Under Takahashi, the Bank of Japan lowered its discount rate from 5–6 percent to about 3 percent (by 1935). Other interest rates followed this downward trend. In 1932, the real call-money rate (a market rate) likewise dropped from about 15 percent to 6 percent and remained at less than 1 percent for the remainder of the Takahashi years.

Partly as a result of this policy, real gross domestic fixed capital formation recovered to its 1929 peak by 1933 and rose steadily thereafter.

#### C. *Deficit Spending*

Until 1932, when Takahashi became Finance Minister, Japanese government borrowing for deficit spending had been done for specific purposes, such as public works, reconstruction, or war. Under Takahashi, however, funds from new debt issued could be used for general government expenditures. Government debt, moreover, was allowed to be financed by selling bonds to the

Bank of Japan, which then resold them to the public. This constituted the beginning of "open market operations" in Japan, a term Takahashi (1936a, p. 579) used in its English form.

Government fiscal policy, which was turning expansionary in Inoue's last year, then switched completely from attempts to cut the budget and reduce debt to deficit-financed spending. Net central government expenditures, which had fallen by 19 percent since their peak in 1928, rose by 32 percent in 1932 and another 16 percent in 1933. Over these two years, increased government consumption and capital formation accounted for 29 percent of the total increase in real GDP.

Of course, some of the rise in government spending was a natural consequence of pressures by the military and emergency expenditures for local relief for farmers because of crop failures. Of the large increases in government expenditures in 1932 and 1933, approximately half were accounted for by increased military spending. By 1935, 78 percent of the total rise in central government expenditures had been in the military accounts. Relief for farm villages also was important, but the bulk of these expenditures came from local jurisdictions, not from the central government.

#### IV. The Keynesian Origin of Takahashi's Policies

The expansionary economic policies advocated by Takahashi were similar to those he had pursued during previous recessions. During his later years, however, his justification for them and his understanding of their impact on the economy seemed to have acquired an increasingly Keynesian nature.

In terms of foreign exchange policy, Takahashi thought the yen's value should be set by the market (1936a, p. 423). Like Keynes, he opposed going back to the gold standard at the prewar parity, and he considered internal price stability to have precedence over external balance (Keynes, 1923, pp. 140-76).

Takahashi's low interest rate policy was Keynesian in the sense that it was based on

the link between the monetary and the real sectors. His perception of this link was not as complete as that in *The General Theory*, but he saw changes in monetary conditions affecting real output through changes in wages and interest rates. Takahashi was skeptical of the quantity theory of money as a basis for policy (1936b, pp. 217-18).

Takahashi justified increased government expenditures, especially for the military, in terms of the expenditure multiplier and the business activity they generated. In October 1929, he demonstrated his knowledge of the Keynesian multiplier in an explanation of what is now considered to be the paradox of thrift. He noted that if an individual were to save new income instead of spending it, the multiplier would be 1. If the money were spent, however, he thought the multiplier would be as high as 20 to 30 (1936c, p. 247).

The fact that Takahashi justified government spending to stimulate employment and economic activity in terms of the multiplier, however, does not mean, as many have argued, that his ideas predated Keynes, or, as one author has postulated, that he could not have given the speech in 1929 before Keynes published his *General Theory* (Shogo Sasahara, 1981, p. 225). The distinctive contribution of *The General Theory* was not the advocacy of a policy of public works expenditure. Such a policy had already been argued by Keynes in 1929 in an influential pamphlet coauthored with Hubert Henderson entitled, *Can Lloyd George Do It?* (Don Patinkin and J. C. Leith, 1977, p. 9). This pamphlet not only explained the difference between primary and secondary effects of government spending, but laid out the idea of the expenditure multiplier.

How Takahashi acquired the concept of the expenditure multiplier is not known, but it is quite likely that he had read the Keynesian description of it by 1929. He was an avid reader of foreign books and periodicals, including the *London Times* (Ministry of Finance, 1977, p. 128). He kept abreast of theoretical developments in economics abroad and used them in his public statements. In a 1933 speech, for instance, he quoted Irving Fisher and used the results of a University of Chicago economic seminar

that he had translated in arguing for a countercyclical fiscal policy (1936a, p. 559). He also advocated several ideas which had appeared in Keynes' earlier writings on money.

Takahashi, however, understood that financing government expenditures by issuing debt was limited by the ability of the public to absorb it. Beyond that it becomes inflationary. In Takahashi's words, "the limit comes when the effect of the additional funds raised by issuing debt has no value in fostering private industry and, therefore, no stimulus on sound development" (1936a, pp. 54-55.) He saw this limit being reached in 1935 when he made the fatal decision to attempt to rein in military spending.

### V. Factors Underlying the Economic Recovery

Regardless of the origin of the ideas behind the policies advocated by Takahashi, it is of independent interest to assess their quantitative impact on the subsequent economic recovery that started towards the end of 1932.

Since the beginning of the recovery coincided with the revision of the government budget, and the subsequent expansion paralleled the continuation of the budgetary deficit in succeeding years, the contribution of Takahashi's fiscal policies to the economic recovery has not been questioned much in Japan. Recently, however, some have noted the strong recovery in private investment during the early phase of the recovery and suggested that the economic expansion was actually led by the private sector (K. Shima, 1983, pp. 108-13).

In order to test the effect of various economic variables on real *GDP*, we use Granger causality tests (C. W. J. Granger, 1969; R. J. Gordon and J. A. Wilcox, 1981). These were done by using an *F*-test to determine whether changes in real *GDP* can be explained by variables other than the lagged value of real *GDP*, itself. The tests were performed by using annual data for the period 1920-40, with the current and two lagged values of several independent variables, of which five were significant. Since only annual data could be employed, current values were also included to capture the feedback process dur-

TABLE 1—GRANGER CAUSALITY TESTS ON JAPAN'S REAL *GDP*, 1920-40<sup>a</sup>

Independent Variable	<i>t</i> -Ratio Current Value	<i>F</i> -Statistics	
		Two Lagged Values	Current and Lagged Values
Consumer Price Index	2.144 <sup>c</sup> (1.608)	2.656 (1.447)	1.771 (0.966)
Export Price Index	3.304 <sup>b</sup> (2.478) <sup>b</sup>	4.009 <sup>b</sup> (1.447)	3.660 <sup>b</sup> (2.179)
Yen/Dollar	1.958 <sup>c</sup>	2.784 <sup>c</sup>	2.119
Exchange Rate	(1.942) <sup>c</sup>	(0.499)	(1.631)
Real Central Government Expenditures	1.641 (1.621)	1.455 (0.774)	4.930 <sup>b</sup> (4.016) <sup>b</sup>
Real Domestic Debt	1.921 <sup>c</sup> (0.790)	0.322 (0.130)	3.316 <sup>c</sup> (3.601) <sup>b</sup>
Real Private Investment	1.683 (1.245)	1.933 (0.432)	1.633 (0.733)

Sources: Underlying data from Ohkawa et al. (various years); Bank of Japan, *Economic Statistics of Japan*, annual issues; *Oriental Economist Yearbook*, annual issues.

<sup>a</sup> The results for money supply, interest rates, and real exports were insignificant and not reported. Although insignificant, the results for real private investment are reported in view of the current debate on its role in the recovery. Figures based on log and level (in parentheses) are shown.

<sup>b</sup> Significant at 5 percent.

<sup>c</sup> Significant at 10 percent.

ing the same time period. Summary statistics from these tests are presented in Table 1.

Note that real private investment had little causal (lagged) as well as contemporaneous (current) impact on real *GDP*. Although, not surprisingly, real central government expenditures and real domestic debt did have a significant contemporaneous impact, they had little causal effect on real *GDP*.

What did have significant causal as well as contemporaneous effects were external price developments, captured by exchange rate and export price movements. It was also found that, in terms of the impact elasticity of the current value, the consumer price index (0.569) had the strongest impact on real *GDP* of all the independent variables.

The above results, however, are subject to the usual interpretational limitations associated with Granger causality tests. Moreover, they are more limited by the use of a relatively long, annual time-series. Use of

monthly or even quarterly data might provide a better basis for interpreting the causal relationships observed among different economic variables, if such time-series were available.

Given these limitations, however, the importance of price factors—primarily brought about by Takahashi's exchange rate policies—in the subsequent economic recovery is clearly indicated. On the other hand, the contribution of fiscal policies, as important as they may be from the point of view of the history of economic thought in Japan, may well have been given too much credit.

## RISK PERCEPTION AND MARKET PERFORMANCE<sup>†</sup>

### Financial Risk and the Burdens of Contracts

By HERMAN B. LEONARD AND RICHARD J. ZECKHAUSER\*

A young artist we know was recently approached by a mail-order marketing company affiliated with a major credit card. She was asked to develop designs for use on sets of high-quality china to be marketed nationally. The company initially offered to purchase the designs on a straight commission basis—our friend would receive a percentage of gross sales. She asked to be paid a fixed fee instead.

This request seems odd. It might indicate that she distrusted her artistic capacity for this task (she didn't), that she would slack off (she wouldn't), or that she distrusted their marketing skills (she did, but she hardly wanted to tell them). The company's royalty proposal provides a financial incentive for quality, but it conveys a mixed message. To induce a large investment of the artist's time, the company should have tried to persuade her that it was confident of selling many sets. The royalty offer suggests instead that the firm fears only a few sets will be sold, and wants to protect itself against excessive artist's fees per set.

The negotiation concluded with the company agreeing to pay an attractive fixed fee. This arrangement placed the marketing risk on the company, which is likely both to perceive it as smaller and to be better able to bear it no matter what its size. It also removed any incentives to undermarket that might have been created by a royalty agreement.

But the contract gives the artist no direct incentive to spend the extra time to make these designs superlative (such efforts would be repaid by attracting future business, however).

This contract clearly attends to financial risk. The effects of variance in the outcome are borne by the party better able to absorb them. But it is difficult to assess the risk-assignment aspects—how much our friend "paid" to get the insurance she bought, or for the negative signal about confidence she had to send to get it—because they are intertwined with a collection of other messages and complicated by other motivations. A basic tenet of economics is that joint gains from trade arise from differences between the parties (Leonard and James Sebenius, 1983). But the parties must simultaneously discover and exploit their differences; thus a contract becomes not merely a division of known gains, but a device for revealing them as well. Even relatively simple contracts are asked to carry a whole collection of informational and incentive burdens. Risk perceptions (Amos Tversky and Daniel Kahneman, 1974), risk preferences, and the chosen allocation of risk between the parties (Kenneth Arrow, 1971) are three elements of the collection; they may be difficult to see through the veil of the others.

#### I. Multiple Burdens

Contracts must carry multiple burdens when outcomes—and possibly inputs—are uncertain or unknown. Financial risk is recognized in the form of contracts: in what will be exchanged, under what contingencies. But this is not the only issue a given contract is designed to resolve, and often it is not the most important one. The form of contracts becomes particularly important when at least

<sup>†</sup>*Discussants:* George Akerlof, University of California-Berkeley; Kenneth J. Arrow, Stanford University; Gary S. Becker, University of Chicago.

\*John F. Kennedy School of Government, Harvard University, Cambridge, MA 02138. We are indebted to Kenneth Arrow, Gary Becker, and Howard Kunreuther for helpful comments, and to Nancy Jackson for editorial assistance.

one party is in doubt about outcomes because of uncertainty about the inputs that can or will be supplied by another.

In the traditional market paradigm, certainty and full information prevail, and the function of contracts is simply to divide the known outcome(s) efficiently. For example, wages must be set so that conditions of competitive equilibrium in labor markets are satisfied. Contracts simply specify exactly what will be exchanged, governed by what contingencies, and at precisely what price. Modern economics, in contrast, has examined a variety of forms of ignorance and the modifications of contracts that may arise to cope with them. Ignorance about random influences on *outcomes* (i.e., pure uncertainty about the future values of random variables) is in many ways the simplest form of missing information. Actual outcomes vary around their expected values; financial theory examines the consequences of that variance in a world where individuals have different perceptions of risk and different aversions to it. It prescribes modifications of contracts that efficiently divide both the expected outcome and the variance, and capture all relevant information possessed by at least a few participants in the market. If these were our only forms of ignorance, and if no information were closely held, financial markets could readily deal with risk, and we would be able to discern that they were doing so.

Two additional major forms of ignorance—about *characteristics* and about *performance*—have important consequences for contracting, however. Signaling theory is concerned with how we use observed purchases, which may include contract provisions offered, to reveal what cannot otherwise be discovered at such low cost (Michael Spence, 1974). Often we can arrange contracts or set conditions before entering contracts that will successfully distinguish people with materially different but unobservable characteristics, even when some of them would prefer to mask the differences. Agency theory starts from the proposition that principals cannot costlessly monitor the efforts or performance of agents they retain (Michael Jensen and William Meckling, 1976; John Pratt and Zeckhauser, 1985). Accord-

ingly, contracts must be concerned with providing motivation—that is, with enforcement (or at least support) of the intended bargain.

Simple contracts cannot always address all of these concerns simultaneously. The needs are at least distinct, and they are often in conflict. By analogy to a lesson of Jan Tinbergen, a few contract parameters may not be enough to address the concerns separately. Moreover, interactions of contract burdens can result in unexpected inefficiencies. For example, signals may be costly to obtain, but once purchased they do not typically affect marginal payoffs, and hence do not distort incentives. But when signaling is part of a complex package that must provide motivation and distribute risk, the resulting imperfect contract often does involve marginal distortions. Were there no risk aversion, such difficulties could be avoided, by merely letting the agent reap all the benefits from the outcome, that is, by selling him the company. If more than one agent is contributing effort, even this scheme will not work.

## II. Worker Selection

These conflicts can arise even when there is no uncertainty about future random occurrences. Consider a firm that wants to hire the best available salesperson—the one who will sell most. Potential workers know exactly how much they would sell, but the firm does not. Each worker has the same reservation wage. Effort is not involved, just human capital (Gary Becker, 1964). The contract must both identify the best salesperson and divide the value of production between the firm and the worker. Clearly, no simple salary offer can distinguish among workers (either all or none would want the sales job, depending on whether the sales salary exceeded the reservation wage). A commission contract does provide this distinction. If the firm knows how good the best salesperson is, it can simply offer a commission rate low enough so that only the salesperson with greatest ability can earn more than the reservation wage. If the firm does not know the maximum ability in the population, it can still arrange the appropriate selection. For example, it can offer the job at auction,

hiring whoever agrees to accept the lowest commission rate.<sup>1</sup>

If we ask more of this contract, it too becomes insufficient. Suppose, for example, that actual sales are distributed around expected values known to workers, and that potential salespeople are risk averse while the firm is not. Then potential sales workers' desires to purchase insurance will conflict directly with the need to reveal which among them is the most able. The equilibrium must involve some use of royalties as a device to distinguish ability levels. But the participant selected through this sieve would prefer that the bargain be in the form of salary only. Similarly, a contract like this may partially reveal and accommodate differences in perceptions of risk, in work disincentives (and therefore prospective effort levels), and other features that both parties cannot perfectly observe—but only in exceptional circumstances will it be possible for a reasonably simple contract to achieve a fully efficient result.

A second example shows the interaction of risk aversion with other contract conditions more fully. Suppose we have three types of potential sales workers, each with reservation wage 100, with risk aversion and human capital (indexed by a normal distribution on output) as indicated:

	Salesperson Type		
	1	2	3
Potential Sales Profit			
Mean	100	110	120
Standard Deviation	10	10	30
Risk Aversion	none	severe	severe

What form of contract will both select the right salesperson for the job and distribute risk efficiently between whoever is selected

and the risk-neutral firm? One strategy would be to offer the firm for sale to the highest bidder, at the price quoted by the second highest bidder. This has the standard incentive compatibility of any Theodore Groves (1973)/Edward Clarke (1971) scheme, but honest elicitation is not enough in this case. Given sufficient risk aversion on the part of bidders 2 and 3, the highest bidder will be 1—the least able of the lot. We can elicit signals about who is best by selling a stake in the firm—for example, we might set a commission rate of 10 percent and give the position to whoever will accept the lowest salary. But this may lead to the selection of bidder 2 over bidder 3.

A less common contract does manage to select the right bidder. Suppose we offer a salary of \$99 and announce that we will also offer profit sharing to whoever bids the lowest share (we refer to such a contract as a "sliver," since a small fractional equity stake in the enterprise has been transferred to the agent). To maintain incentive compatibility, the sharing rate will be whatever is bid by the second lowest bidder. The fact that the fraction is small insures that the effect of risk aversion is removed, and the sliver system selects the most productive salesperson.<sup>2</sup>

It may not be practical to offer a profit-sharing plan of the sliver type—the commission rates may be so low as to seem silly, for example. Another contract, which we have not seen used, will work instead. Let the firm announce that it will pay \$99 in salary plus a \$2 bonus (an amount small enough not to incur risk-aversion losses) to whomever it hires if he or she meets a sales quota. The potential worker who volunteers to accept the highest quota will be hired, with the quota set at the level offered by the second highest bidder, for incentive compatibility.

<sup>1</sup>In Appendix I (available on request), we spell out a more elaborate example in which neither a simple salary offer nor a commission offer successfully separates workers by ability in a competitive labor market setting. Only a combination of salary and commission can support an efficient equilibrium. Even this more complex contract structure is unable to provide appropriate separation when we add to the contract the further burden of allocating risk efficiently.

<sup>2</sup>This contract breaks down as a selection device, however, if different bidders have different reservation wages. Suppose, for example, that bidder 3 has a reservation wage of 105. Given an excess productivity of 10, he or she is still the best candidate for the job. But now a contract of \$99 (or any constant) plus a small equity stake will not be enough to separate bidder 3 from bidder 2.

The contract is a small bet, so risk aversion will not play a role. This contract based on a bonus for meeting a negotiated performance standard thus permits identification of the most able salesperson and appropriately allocates risk.

Both the need for a mechanism for revealing personal characteristics and the need to build in performance incentives are often in direct conflict with the parties' preferences for dividing risk. People generally know more about their own characteristics than others know about them, and they often have a better assessment of the risks involved (if any). Consider the entrepreneur-inventor approaching venture capitalists. The inventor may be unduly optimistic about the market's reception of new products, but almost surely has a better technical understanding of the potential—and the problems—of the proposed product. This more accurate assessment comes bundled with a conflict of interest about revealing it truthfully. Any contract with a supplier of capital must bear the burden of revelation as well as division. The most natural way to do this would be to offer contracts that will only be accepted by inventors with high subjective probabilities that their inventions will succeed—that is, contracts that will pay off handsomely only if the product is a considerable commercial success. But these are exactly the contracts that impose the greatest financial risk on the entrepreneur, the party to whom it is probably most costly.

If we resolve this conflict in favor of appropriate risk spreading—pay a fixed fee for the patent and put the inventor on salary—the contract can no longer reveal honest risk assessments by the most knowledgeable party. If we offer a strongly revealing contract—a small salary with a large royalty rate on sales beyond the breakeven point—the contract cannot allocate risk bearing efficiently. Moreover, the magnitude of the risk burden will vary directly with the incentive for the entrepreneur to work—when the acceptance of risk is being used as a signaling device, it often distorts work incentives at the margin. (This problem is not unique to signaling through risk, but in many situations the signal, once purchased, does not

alter marginal incentives.) Neither extreme on this contracting spectrum is particularly attractive. In practice, we are likely to observe some form of compromise—which means that full optimality is sacrificed and that it may be hard to discern just how (and how much) the market arrangement has recognized financial risk.

### III. Responses to Risk Sharing

Providing performance incentives in contracts also frequently militates against appropriate risk spreading. Consider the problem of rewarding managers. For a collection of well-understood reasons, shareholders want the firm not to be risk averse. But managers face career risk within the firm and are themselves understandably risk averse. As a result they may be unwilling to undertake sufficient risk. We often observe incentive contracts for managers (stock options, for example) that at least partially balance this (inefficient) caution. They are valuable only when the company does quite well—an event made more probable if the managers take greater risks. (A standard result of options theory is that ownership of options makes one risk preferring, or less risk averse.) But this performance incentive, deliberately designed to offset the risk aversion of managers, must proceed precisely by imposing greater risk on them. Indeed, studies of compensation for high-level executives have found very high levels of risk borne by the agents—evidently, the advantages from performance inducements and the selection gains from attracting risk takers compensate the losses from poor risk spreading. This makes it difficult to uncover the elements of these contracts that recognize and deal with financial risk—they are deeply intertwined with other burdens the contracts are carrying.

The need for incentives to balance the nonlinearity of rewards with performance can run in the other direction. Western legal tradition confers limited liability on shareholders, producing an asymmetry in payoffs around the point of bankruptcy. When a firm is near bankruptcy, it is protected from the full adverse consequences of any gamble, and this may induce risk-preferring behavior.

Indeed, it results in a fundamental managerial principle: "when your back is against the wall, roll the dice." Under these circumstances the firm may engage in gambles for which the risk-adjusted rate of return is below the risk-free rate, that is, it may accept lotteries involving a mean-sacrificing spread (*MSS*) of outcomes.<sup>3</sup>

#### IV. Robustness and Optimality

Since the many burdens contracts are asked to carry are often in conflict, full optimality is difficult to achieve.<sup>4</sup> But why do we not more often see more complex contracts, tailored to address a wider set of concerns? One answer, often advanced, is that customizing contracts is expensive. We propose an additional reason: like creatures too carefully adapted to a particular ecological niche, highly specialized contracts are vulnerable to small changes in conditions. For example, if we must address only risk aversion and selection on the basis of ability through a contract offer, a contract offering a high salary and a small equity stake in the outcome will suffice (the small equity stake attracts the more able; the fact that it is small means that it does not impose much risk and therefore involves no real loss due to risk aversion). If we need not worry about risk aversion, but must provide a marginal incentive for effort along with a selective mechanism to identify the more able, then a large equity stake in the outcome will generally be appropriate. In either case, a simple contract, specialized to address the precise conditions defining the contracting context, suffices.

<sup>3</sup>Given a risk-free rate and a market premium for risk, a gamble is a mean-sacrificing spread if it involves below-market compensation for risk bearing. The expected return may be positive; it is still a sacrifice if the mean rises by less than we would expect, given the risk. Firms near bankruptcy might be induced to accept even gambles that involve an absolute reduction in mean in return for a sufficiently large spread. The propensity to engage in *MSS* can be offset by instruments such as bonds convertible to stock at the bondholders' option.

<sup>4</sup>In Appendix II (available from the authors), we describe a scheme for categorizing contracting situations and contract types, and comment on whether optimality can be achieved under various combinations of them.

Unfortunately, a small departure from the specified underlying conditions will make either contract seriously deficient. If agents are risk averse and we must both select the best workers and encourage effort at the margin, neither a small nor a large equity stake will work well—one provides too little incentive for effort, the other too much risk. Adding even a small payoff from effort to a contract context that originally involved only selection and risk aversion could dramatically alter the contract stipulations required to achieve optimality. The carefully arranged near optimality of a specialized contract crafted to address a given set of conditions can often be seriously upset by even a small dose of some other condition.<sup>5</sup> Thus familiar contracts, frequently simple in form, may not only be only cheaper to arrange, but may also be more robust. That is, they may achieve reasonable, though imperfect, results across a wider range of contracting conditions. This may be an important part of their attraction. Simplicity and robustness are, of course, not synonymous; we are merely observing that contracts designed to address fewer special features seem less likely to be blindsided by others.

The attractiveness of simple familiar contracts, in turn, makes it difficult to identify and measure the extent to which financial contracts appropriately recognize risk. Our ignorance is much more profound than simple market uncertainty. Contracts must specify divisions of benefits, but they must also

<sup>5</sup>In many contracts, the degree of optimality obtained is a smooth function of the underlying conditions, and the characteristics of the optimal contract vary continuously as a function of the burdens being carried. For example, a small change in the risk aversion of the agent in a contract balancing performance incentives against risk spreading would call for only a small adjustment in contract terms. By contrast, when selection is involved a small alteration in conditions can lead to a switch in which candidate gets the job, and a consequent dramatic shift in the degree of optimality obtained. A major change in the form of the contract may be required to maintain optimality. For example, our negotiated quota arrangement can fail if the three salesmen have different reservation wages—and even a small change in reservation wages can take us across the boundary.

provide motivation even as they rely on it, and provide information about personal characteristics even as they make use of it. Because contracts must simultaneously address all of these needs, the result is either complicated arrangements or, more typically, uncomfortable compromises within simple contracts. This makes it difficult to see how any particular issue is being dealt with. We see only the congealed Gordian knot; the separate strands can no longer be distinguished.

# Are Individuals Bayesian Decision Makers?

By W. KIP VISCUSI\*

There has been increasing interest in whether normative models of individual choice under uncertainty accord with actual behavior. These concerns have been much greater than in other economic contexts because of the particularly severe demands such decisions place on the rationality of the decision maker. The limitations of these decisions have widespread consequences, as they provide the rationale for many governmental efforts to regulate the risks people face. Here I explore the issues raised by a Bayesian decision framework, focusing particularly on my analyses of worker and consumer behavior.

## I. Risk Perceptions

Ideally, individuals should fully understand the risks they face before making decisions with probabilistic outcomes. In most instances, extensive experimental evidence is not available, so that individuals must rely on their subjective probabilistic judgments. Such assessments will clearly not always be accurate and may be systematically biased as well. Precise analysis of the nature and extent of such biases is impeded by the paucity of data on individuals' probability assessments and the actual risks that they face.

My analysis (1979) of worker risk perceptions focused on survey data for which I linked an objective risk index (the BLS injury rate for the worker's industry) and a measure of the worker's subjective risk perceptions—a dummy variable for whether or not the worker's job exposed him or her to dangerous or unhealthy conditions. The expected positive correlation was observed, but such evidence can only be suggestive because the workers did not scale the risks in probabilistic terms.

To refine this evidence, in my article with Charles O'Connor (1984) we presented over 300 chemical workers a linear scale that they would use to rate the hazards of their jobs. This scale was constructed in a manner that made it possible for us to compare workers' responses to objective measures of the chemical industry risk. In particular, each rating could be converted into an equivalent level for the BLS injury and illness rate. Overall, workers' subjective risk assessments were above the reported injury and illness rate for the chemical industry, which one would expect since health risks are notoriously under-reported. What was particularly noteworthy is that once the long-term chemical hazards were excluded from consideration (for a subsample that was told that they would be working with sodium bicarbonate instead of their present chemicals), the subjective risk perceptions were identically equal to the published accident rates. Although one would be hard-pressed to claim that such a fortuitous result implies that all job risk perceptions are unbiased, there does appear to be a strong correspondence between actual and perceived risks for a major class of risks that people face.

When asked to rate their job risks using a linear scale or when asked about whether or not their jobs pose a hazard, most respondents give plausible risk-perception assessments. These assessments are much more accurate than the responses in studies that frame the risk perception issue in relative terms (for example, whether or not the respondent believes he or she is an above-average risk driver), where systematic optimism has been observed. Some observed biases in past studies may be due to the manner in which the risk-perception question is framed, rather than any underlying shortcoming in individual behavior.

It is well known, however, that individuals have particular difficulty in thinking about low probability events. An especially influential study is that of Sarah Lichtenstein et al.

\*Professor and Director, Center for the Study of Business Regulation, Fuqua School of Business, Duke University, Durham, NC 27706.

(1978), who explored fatality risks, ranging from tornadoes to strokes and homicides. The pattern they observed was that individuals overassessed small risks of death and underassessed large risks.

Although these biases in risk perception are widely cited as evidence of irrationality, in my forthcoming article I show that such a pattern is exactly what one would expect from a Bayesian learning process. Let  $p_i^*$  be the probability of death from accident category  $i$ ,  $s_i$  be the actual risk from category  $i$ , and  $p$  be the prior risk assessment before knowing the category to which the accident belongs. If individuals behave rationally and their probability assessments are characterized by a *beta* distribution, one can show that

$$(1) \quad p_i^* = (p + \psi_i s_i) / (1 + \psi_i),$$

where  $\psi_i$  is the relative informational content associated with category  $i$  compared with the individual's prior. More specifically,  $\psi_i$  represents the equivalent number of Bernoulli trials that the individual acts as if he (or she) has drawn for category  $i$  accidents divided by the number of trials he acts as if he has observed when forming his prior  $p$ .

Individuals' risk perceptions should be a weighted average of the true risk and their prior, where the weight depends on how much information they have about category  $i$ . The value of the prior risk assessment  $p$  was not ascertained in the survey so I used two different proxies for this risk in separate equations. The first was an Akerlof "lemons" model measure—the average of all of the risks in the sample. The second proxy used was the reference point that each respondent was given in the survey before assessing the risks (either motor vehicle deaths or electrocutions).

The subsequent empirical estimates were consistent with the linear relationship specified in equation (1). For small risks, individuals revised their prior beliefs downward, but not fully, leading to overestimation of the risk. Similarly, for large risks the prior is revised partially in the upward direction, leading to an underassessment of the risk. It

is particularly noteworthy that the relative weight  $\psi_i$  placed on the true risk level was not significantly correlated with the degree of risk so that there was no bias in the manner in which probabilistic beliefs are revised in the direction of the true risk.

Overall, the evidence suggests that individuals may have reasonably accurate perceptions of risks that have a fundamental impact on their welfare. Risk perceptions for other more remote hazards are less precise, and the observed biases are exactly what one would expect from a rational, Bayesian learning process. The inadequacies in risk perception also do not appear to be clearcut in either direction. The overestimation of small risks and underestimation of large risks represents a more complex type of market failure than is reflected in the usual economic models incorporating biases in risk perception, which typically assume that risks are underestimated.

## II. The Role of Learning

The cornerstone of the Bayesian approach is the learning process by which individuals update their risk perceptions. This learning process was implicitly involved in the formation of the risk perceptions discussed above. In my 1979 study, I analyzed the consistency of workers' risk perceptions with the possibility of on-the-job learning using cross-sectional data. Workers who had experienced a job injury or viewed other working conditions as being unpleasant were more likely to view their jobs as being dangerous, controlling for the industry risk level and related factors. One cannot be confident based on this evidence that workers do in fact learn, since the results may simply reflect the correlation of high initial risk assessments with risky job attributes.

To explore the evolution of workers' risk judgments, O'Connor and I undertook an experiment with chemical workers at four plants. Each worker was shown a label for a chemical (either sodium bicarbonate, chloroacetophenone, asbestos, or TNT) and was told that this chemical would replace the chemicals on his present job. Workers' risk perceptions responded in the expected man-

ner, falling for sodium bicarbonate and rising for the other three chemicals. Since the true job-specific risks posed by these substances and the worker's other job risks is not fully understood, the most that could be concluded is that the prior probability assessments were revised in the correct direction.

Based on the worker responses, it was possible to estimate the key parameters in equation (1) that are associated with the label's impact—the risk  $s_i$  implied by the label and its relative informational content  $\psi_i$ . Except for sodium bicarbonate, the implied risks  $s_i$  did not differ greatly. There was, however, a substantial difference in the relative informational content  $\psi_i$  of the hazard warnings. The unfamiliar chemical chloroacetophenone had a  $\psi_i$  value of 1.3, implying an informational content just above that of the worker's prior, whereas TNT had a dominant  $\psi_i$  value of 31.4.

These results suggest that people can process risk information in the expected direction, but that it is the informational content of the message, not simply the associated risk level, that is instrumental. The ineffectiveness of informational campaigns to promote seatbelt use and to discourage cigarette smoking are not unexpected, since the new information contained in such ads is not great. These efforts might be viewed more accurately as being policies of exhortation rather than information.

While available evidence suggests that individual learning about risks can often play an important economic role, this learning process may not be ideal. The critical reviews by Amos Tversky and Daniel Kahneman (1974), Kenneth Arrow (1982), and Baruch Fischhoff and Ruth Beyth-Marom (1983) have identified a number of systematic shortcomings. Individuals tend to exaggerate the completeness of hypothesis sets, ignore the base-rate frequency of outcomes, and more generally fail to fully understand the laws of probability. Individuals may behave in the general spirit of Bayesian decision makers in the learning process, but this behavior does not conform identically with an optimal learning process. The degree to which the various shortcomings identified in lab-

oratory experiments affect market behavior involving risks has not yet been ascertained.

### III. Risk Perceptions and Individual Behavior

A number of studies have linked higher wages to job risks, consistent with Adam Smith's theory of compensating differentials. This is the most basic test of rational decisions involving uncertainty, and the supporting evidence is strong and quite diverse. Compensating differentials have been estimated for a large number of data sets using a variety of risk measures. It is particularly noteworthy that the observed premiums are roughly similar whether the risk variable is an objective hazard measure (for example, the industry death rate), or a measure of subjective risk perceptions (see my 1979 study and my article with O'Connor). Since it is the subjective perceptions that are instrumental from an economic standpoint, these results suggest that the fundamental behavioral assumption of the theory is satisfied.

Although the risk level is the only feature of the job risk that is of consequence in a single-period model, in a multiperiod model in which there is the possibility of terminating the job either through a job change or one's death, I have shown that the precision of the risk judgments is an addition concern. The underlying rationale is that in this class of two-armed bandit models, loose prior beliefs are preferred because they offer the potential for greater gains from experimentation with the uncertain job. As predicted, chemical labels associated with higher  $\psi_i$  values lead to higher worker reservation wages, as do labels with higher  $s_i$  values. Both the risk level and its precision affect a lottery's attractiveness if one is incurring a sequence of such lotteries that may be terminated conditional on an unfavorable outcome.

Although these results are consistent with optimal behavior in uncertain contexts with learning, not all observed risk-dollar tradeoffs imply that decisions are accurate. In a recent study of consumer attitudes toward low probability events (on the order of 1/100,000 risk annually), Wesley Magat and I (1984) ascertained consumers' valuations of different health outcomes. The results suggested

implausibly large risk-dollar tradeoffs. For example, there was an implied externality value to society at large of roughly \$200,000 to prevent a hand burn from drain cleaner that would be temporary, but severe enough to require medical treatment. Individuals clearly have difficulty making decisions involving low probability events, and in this instance there is evidence of excessive valuation of the risks. These biases in turn may lead to alarmist decisions and excessive governmental regulation. In other cases the low risk may be ignored, creating biases of the opposite nature.

Once learning is introduced as an element, individuals will continually reassess the appropriateness of the risks and its rewards in relation to their other opportunities. The tendency of individuals to experiment with activities posing dimly understood risks will be fostered by the structure of the statistical decision problem. Individuals will display a predilection for risky jobs and other lottery sequences associated with loose priors since these offer the greatest gains from experimentation.

As predicted by these two-armed bandit models, there is a significant relationship between job risks and worker decisions to switch jobs once significantly adverse information is acquired. Results for five data sets reported in my 1979 study indicate that job risks raise worker quit rates, boost quit intentions and job-search activities, and shorten paths of employment at the firm, controlling for health status and a variety of other factors. Indeed, job risks may account for as much as one-third of all manufacturing quit rates.

In addition to the positive effect of the risk level on quitting, the aforementioned work on chemical labeling produced a positive influence of the relative precision  $\psi_i$  of the risk information on quit behavior. This impact is also consistent with an optimal experimentation process since more precisely understood risks are less attractive because of the diminished value of the experimentation process associated with them. The overall job choice process is consistent with a model in which individuals start jobs with imperfect information, revise these beliefs in Bayesian

fashion based on their on-the-job experiences, and alter their job choice if this information is sufficiently adverse.

Consumers likewise respond to risk information in an adaptive manner. In our study of consumer product labeling, Magat and I found that labels including risk warnings increased the frequency of consumer precautions by up to 33 percent, as compared with labels without warnings. These results may understate the role of learning to the extent that consumers' prior beliefs have been conditioned by past knowledge of the product. For example, even without a hazard warning, more than half of all consumers would store drain cleaner in a location to which children did not have easy access.

Overall, individuals do not possess perfect information about the risks they face, but they do have opportunities to revise these beliefs based on their experiences. The observed behavior patterns are consistent with the principal predictions of a Bayesian learning process and subsequent adaptive behavior.

Although this behavior is broadly consistent with a Bayesian framework, these decisions do not always coincide with optimal behavior. As with other optimizing models in economics, Bayesian decision models represents an often powerful tool, but also a tool that may not accurately reflect how decisions are made. The expected utility hypothesis that is central to these models has long been questioned. In some contexts, inconsistencies in individual choices have been observed. There also appears to be asymmetric treatment of gains and losses, as well as special attention paid to certain outcomes. Moreover, in an actual market context in which one would have expected risk-averse consumers to purchase heavily subsidized flood and earthquake insurance, Howard Kunreuther et al. (1978) have shown that they failed to do so. As a result, individuals may respond in a manner that is broadly consistent with Bayesian decision theory, but the normative guidelines of that theory may not always be met.

Nevertheless, Bayesian models remain a useful optimizing framework for analyzing economic behavior. In some cases, the ex-

isting biases in behavior may be predicted by proper application of the Bayesian model. In others, there may be shortcomings in the manner in which individuals make decisions.

The implications of these inadequacies for the nature of the market failure are not always clear-cut. Risks may be ignored, leading to a supra-optimal level of risk, or they may be over-assessed, as shown in studies of small fatality risks. The nature of the market failure is likely to be more complex than is captured in standard models of imperfect information. There may be either inadequate or excessive attention to risks, depending on the particular context. Much remains to be learned about the shortcomings of individual decisions, the magnitude of these shortcomings, and their implications for market performance.

# Ambiguity and Insurance Decisions

By ROBIN M. HOGARTH AND HOWARD KUNREUTHER\*

Imagine that you are in the insurance business and are preparing to quote premiums for two risks that can be characterized as follows:

In Situation *A* there is a potential loss of \$100,000 and your best estimate of this loss occurring within the period covered by the insurance is .01. Moreover, your estimate of the probability is based on the opinions of several experts all of whom agree on the .01 figure.

In Situation *B* there is also a potential loss of \$100,000. However, whereas your best estimate of the probability of this loss occurring within the contract period is .01, this figure is a compromise reached after considering the widely different estimates furnished by several experts.

When comparing these two scenarios, many persons deem Situation *B* to be inherently more risky than Situation *A*, such that the premium required to insure the latter would be larger than for the former. However, it is important to note that this behavior contradicts the expected utility model which economists have typically used to analyze insurance decision making (see Isaac Ehrlich and Gary Becker, 1972). The reason is that this model does not distinguish between cases where people do or do not experience uncertainty or ambiguity about their estimates. However, as demonstrated by Daniel Ellsberg (1961) and others (for example, see Selwyn Becker and Fred Brownson, 1964) in experimental settings, ambiguity or "uncertainty about one's uncertainty" does

affect choice. On the other hand, if one believes that ambiguity affects behavior in markets, one needs a model that predicts how such effects occur and when they are important. Our purpose here is to explore the predictions of such a model with respect to the market for insurance.

First we sketch a psychological model of probabilistic judgment under ambiguity developed by Hillel Einhorn and Hogarth (forthcoming). This is then used to predict how both consumers (buyers) and insurance firms (sellers) are likely to react toward differing degrees of ambiguity. A brief summary of the results of experiments designed to test these predictions are presented. Finally, we discuss these results in relation to real world phenomena as well as considering possibilities for future empirical research. We particularly note the importance of developing and testing precise, falsifiable models to complement or challenge implications of the expected utility model since naturally occurring data frequently lack the power to provide stringent tests of the latter.

## I. Ambiguity and Choice

A model of how people assess probabilities of events in ambiguous circumstances has recently been proposed and experimentally tested by Einhorn and Hogarth. The model is based on the following three principles.

1) People are first assumed to anchor on an initial estimate of the probability. Let  $p$  represent the anchor and note that it may be based on past experience, suggested by an analogous situation, or even the figure provided by an expert. The anchor is then adjusted by imagining or mentally simulating other values that the probability could take.

2) The greater the degree of ambiguity experienced, the more alternative values of the probability are simulated and the larger the weight given to such values in the final

\*Graduate School of Business, University of Chicago, Chicago, IL 60637, and Wharton School, University of Pennsylvania, Philadelphia, PA 19104, respectively. We are grateful to Colin Camerer, Hillel Einhorn, Jack Hershey, and Paul Kleindorfer for helpful comments on an earlier version. This research is partially supported by NSF grant SES-8312123 and a contract from the Office of Naval Research.

assessment. Thus, when experts disagree on a probability estimate, people are assumed to imagine more alternative values compared to situations where the experts agree.

3) The weight given in imagination to alternative values of the probability that are greater or smaller than the anchor  $p$  depends on the individual's attitude toward ambiguity in the particular situation.

Let the adjustment to the anchor be represented by  $k$  so that the assessment of the ambiguous probability, denoted  $S(p)$ , is given by

$$(1) \quad S(p) = p + k.$$

To allow for the effects of ambiguity, Einhorn and Hogarth decompose  $k$  into two parts that capture forces favoring positive and negative adjustments, respectively. The positive force reflects the weight given to possible values of the probability above the anchor and is taken to be proportional to  $(1-p)$ ; the negative force reflects the weight given to values below the anchor and is proportional to  $p$ . In both cases, the constant of proportionality is a parameter  $\theta$  that represents the amount of perceived ambiguity in the situation ( $0 \leq \theta \leq 1$ ). In other words, the effect of possible values of the probability above the anchor are modeled by  $\theta(1-p)$ , of those below by  $\theta p$ , and  $k$  is the net effect of positive and negative adjustments from the anchor. However, to account for the fact that values above and below the anchor may be differentially weighted in imagination,  $\theta p$  is adjusted to the form  $\theta p^\beta$  where  $\beta (\beta \geq 0)$  represents the person's attitude toward ambiguity in the circumstances. That is, when  $\beta = 1$ , equal weight is given to imaginary values above and below the anchor; when  $\beta > 1$ , more weight is given to larger values; and for  $\beta < 1$ , more weight is given to smaller values. This leads to the model

$$(2) \quad S(p) = p + \theta[(1-p) - p^\beta].$$

Note that in this model  $\theta$  (i.e., perceived ambiguity) determines the amount of the adjustment, whereas  $\beta$  in conjunction with the level of  $p$  determines its sign. Thus, when  $p$  is low, the adjustment will tend to be

positive; however, as  $p$  increases, the adjustment will become negative. Moreover, the point at which the adjustment starts to become negative depends on  $\beta$ . That is, when  $\beta = 1$ , the "cross-over" point is at  $p = .5$ ; for  $\beta < 1$  this occurs when  $p < .5$ ; and for  $\beta > 1$  when  $p > .5$ .

Now assume that the price a consumer is prepared to pay for a given level of insurance coverage is a monotonically increasing function of  $S(p)$ . Furthermore, let  $C(p)$  denote the premium a consumer is prepared to pay for this coverage when the probability of the loss can be precisely estimated, and  $CA(p)$  that when the consumer is ambiguous. Assume further that when facing the ambiguous probability of a loss,  $\beta$  is not a small value (see discussion above). These assumptions imply the following predictions:

1) when  $p$  is small, the ratio  $[CA(p)/C(p)]$  will be greater than one indicating "ambiguity aversion"; 2) as  $p$  increases,  $[CA(p)/C(p)]$  will decrease and eventually become smaller than one thereby indicating "ambiguity seeking." Denoting the premiums that firms are prepared to charge with precise probabilities as  $F(p)$ , and  $FA(p)$  for premiums under ambiguity, similar predictions can be made for firms—but with one exception. The exception is that one would never expect firms to charge less than expected value. Therefore, for firms, the prediction is that the ratio  $[FA(p)/F(p)] > 1$  for small probabilities but that this ratio will decrease as  $p$  increases.

## II. Experimental Evidence

We have collected experimental data testing the above predictions in a series of questionnaire experiments involving some 500 individuals who were participating in undergraduate, graduate and executive program courses at the University of Chicago and the Wharton School. Most of these subjects had been exposed to courses in economics and statistics and thus were relatively sophisticated concerning insurance. Since all the experiments produced similar findings, we only report here some results from two experiments (for full details, see our 1984 paper).

In the first experiment, 113 University of Chicago MBA students responded to questionnaires administered in a class on decision making. The experimental stimulus concerned the owner of a small business who was considering insuring against a potential loss of \$100,000 from claims due to a possible defective product. Subjects played the role of either the owner of the business (buyer) or the head of the department in a large insurance company (seller) who was responsible for setting premiums. Each subject responded to both the ambiguous and nonambiguous versions of the stimulus (see below) at one level of the anchor  $p$  in an experimental session during which responses were also made to questions that were not related to this study. In all, four levels of  $p$  were investigated,  $p = .01, .35, .60$ , and  $.90$ . In both the ambiguous and nonambiguous cases a specific probability level was provided in the stimulus (for example,  $.01$ ). However, a comment was also added as to whether one could "feel confident" (non-ambiguous case) or "experience considerable uncertainty" (ambiguous case) concerning the estimate. Uniformity of perceptions of ambiguity was controlled by describing the situations by the same words in both the consumer and firm versions.

Table 1 reports median prices of the minimum premiums firms were prepared to charge and the maximum premiums consumers were prepared to pay, together with the ratios of ambiguous to nonambiguous prices at each probability level. Note that in the nonambiguous condition, the median prices are close to expected value for both firms and consumers. However, there are marked differences in the ambiguous case. For firms, premiums in the ambiguous condition exceed those in the nonambiguous case at all levels except  $p = .90$ . Consumers, on the other hand, are only prepared to pay more in ambiguous circumstances when the probability of loss is low (i.e.,  $p = .01$ ). At  $p = .35$ , consumers' maximum prices are the same for both levels of ambiguity and for larger probabilities ( $p = .65, .90$ ) they exhibit ambiguity preference in that maximum prices under ambiguity are lower than when there is no ambiguity. These results are consistent

TABLE 1—MEDIAN PRICES FOR INSURANCE<sup>a</sup>

Probability Levels	Ambiguous (1)	Nonambiguous (2)	Ratio
			Col. (1)/ Col. (2)
Consumers' Willingness To Pay			
.01	\$1,500	\$1,000	1.50
.35	\$35,000	\$35,000	1.00
.65	\$45,000	\$65,000	.69
.90	\$60,000	\$82,500	.73
Firms' Supply Price			
.01	\$2,500	\$1,000	2.50
.35	\$52,500	\$37,500	1.40
.65	\$70,000	\$65,000	1.08
.90	\$90,000	\$90,000	1.00

<sup>a</sup> Loss = \$100,000; a complete statistical analysis of these data supporting the statements made in the text is to be found in our earlier paper.

with the predictions of the Einhorn-Hogarth ambiguity model.

Whereas the above analysis is useful for testing the predictions of the ambiguity model across the range of  $p$ , it is less illuminating from a market perspective. The real issue here is whether willingness to trade on the part of firms and consumers is also affected by ambiguity. This issue was tested in a second experiment, also involving University of Chicago MBA students, who were again assigned either the roles of consumers or firms. Using the same scenario as the previous experiment, subjects were required to respond by stating whether they would trade ("Yes" or "No") at a given price. Having answered this question, subjects turned a page in their experimental booklets and were asked the same question with respect to a different price. To simulate trading conditions, the second price for consumers was lower than the first, whereas the reverse order was used for firms. Since the market for insurance typically covers situations where probabilities of losses are small, we only report here data for  $p = .01$ . The prices quoted were \$1,500 and \$3,000 and the results of this experiment are presented in Table 2. The results of this experiment are consistent with our earlier findings. Consumers are prepared to buy insurance at premiums well in excess of expected value for a low probability event ( $p = .01$ ). Moreover, there

TABLE 2—PERCENTAGES OF SUBJECTS PREPARED TO TRADE AT GIVEN PRICES<sup>a</sup>

	Prices Offered		n
	\$1,500	\$3,000	
Consumers:			
Ambiguous	87	83 <sup>b</sup>	23
Nonambiguous	77	50	22
Firms:			
Ambiguous	16	36	25
Nonambiguous	67 <sup>b</sup>	87 <sup>b</sup>	15

<sup>a</sup>Potential loss = \$100,000;  $p = .01$ .

<sup>b</sup>Differences between ambiguous and nonambiguous significant ( $p < .01$ ).

is greater willingness to insure at high prices when ambiguity is present than when it is not (83 vs. 50 percent). Some firms are also willing to provide insurance for such events. In addition, as the price increases, more firms are prepared to do business in both the ambiguous and nonambiguous cases. However, there is a marked difference in willingness to insure at the stated prices between the ambiguous and nonambiguous cases, that is, 16 vs. 67 percent at \$1,500, and 36 vs. 87 percent at \$3,000.

### III. Implications for Market Behavior

The effect of ambiguity can be precisely isolated in experimental situations, but this becomes far more difficult in natural settings. Insurance markets are rich contexts for studying ambiguity because insurers can always specify a maximum amount of coverage, but may be highly uncertain as to the probability that they will experience a loss of this magnitude. This effect of ambiguity combined with problems of adverse selection, moral hazard, and fear of bankruptcy may result in limited insurance markets. Consider the following two illustrations.

Less than 5 percent of California homeowners purchase earthquake coverage despite their belief that they will receive only limited aid from the federal government in the event of a large loss (Kunreuther et al., 1978). Insurance firms, on the other hand, charge high rates for coverage which may partially explain lack of consumer interest. Over the sixty-year period since coverage has

been offered in California, \$269 million in total premiums have been collected and only \$9 million in losses have been experienced (Arthur Atkisson and William Petak, 1981). These figures by themselves may not be unreasonable if there is a chance that a large earthquake would create huge losses. Furthermore the spector of bankruptcy could restrict this coverage to only large firms who would then have some monopoly power. The counterargument is that damage to residential homes is relatively minor even in a severe earthquake, so that all insurance firms should have an interest in providing coverage at more reasonable rates.

Special institutional arrangements have emerged for dealing with insurance against low probability high loss events. For example, the Price Anderson Act passed in 1957 currently offers \$160 million insurance protection by the private sector to cover nuclear accidents, with the government handling potentially large losses up to a maximum of \$560 million. The industry feels that it will be extremely difficult to increase coverage of private insurers on a voluntary basis due to the ambiguity associated with the probability of a catastrophic event (Alliance of American Insurers et al., 1979). Similarly, the passage of a federal-private flood insurance program in 1968 and the provision of political risk insurance, primarily by the Overseas Private Investment Corporation, are examples of programs for handling events where the probability of a given loss is ambiguous and where private insurers have provided only limited coverage.

Our principal reason for focusing on ambiguity is that it affects the way human judgment and choice deviates systematically from the rational models underlying much of economic analysis when both consumers (buyers) and firms (sellers) have the same information. However, instead of simply documenting another instance where the expected utility model fails to predict behavior (see Paul Schoemaker, 1982), we have specifically tested the implications of a model that does account for the effects of ambiguity. Note also that our model is similar *in spirit* to analyses of insurance markets that are based on the expected utility model. That is, start-

ing from some propositions about human choice behavior at the individual level, we proceed to make and test predictions at the aggregate market level. Moreover, we handle real phenomena that the expected utility model essentially assumes not to exist.

The impact of ambiguity on insurance markets seems to be particularly important for low probability events where there are limited opportunities for learning over time. For some events (for example, fire, life), consumers may have limited opportunities to learn while insurers have a wealth of experience from their claims files. Both parties may be uncertain as to the probabilities of other events (for example, earthquakes, chemical plant accidents etc.) due to limited past experiences and imperfect causal models. There is a need for future research to determine the extent of the ambiguity surrounding probabilities of different events consumers and insurers face, the impact this has on the premium structure and the extent of the market.

There is also a need for more theoretical and experimental work regarding the effects of "uncertainty about uncertainty" on behavior. Market-based experiments in the spirit of Charles Plott (1982) and Vernon Smith (1982) can further extend the questionnaire approach of this study to settings that mimic market conditions more accurately.

Finally, we recognize that ambiguity is but one of a number of phenomena such as regret (David Bell, 1982) and the context or "framing" of decisions (Amos Tversky and Daniel Kahneman, 1981) that can have important impacts on behavior. Nonetheless, we are impressed by the fact that ambiguity is a significant aspect of much economic activity and believe that the topic merits greater attention than has been the case to date.

# UNCERTAINTY, BEHAVIOR, AND ECONOMIC THEORY<sup>†</sup>

## Origin of Predictable Behavior: Further Modeling and Applications

By RONALD A. HEINER\*

Economic theory is founded on the assumption that agents act "as if" they are able to maximize according to well-behaved preferences, regardless of how complex their decision problems might be. Consequently, the theory has never investigated the consequences of a genuine gap between an agent's decision-making *competence* and the *difficulty* of a decision problem (called a *C-D* gap). In a recent paper (1983; hereafter called the "Origin" paper), I outlined a general theory for investigating the latter possibility. A major theme was that recurrent pattern in behavior arises because of decision-making uncertainty due to a *C-D* gap; so that uncertainty becomes the basic source of predictable behavior. Here I discuss certain theory topics that were only sketched in the Origin paper, and briefly suggest a few related applications. To pursue these objectives, I begin with a short restatement of the *reliability condition* introduced in the Origin paper.

### I. The Reliability Condition

The following condition determines whether an agent will benefit from allowing itself the flexibility to select an action  $a$  instead of other choosable actions in its behavioral repertoire, denoted  $A$ .

$$(1) \quad \frac{r_a}{w_a} > \frac{l_a}{g_a} \cdot \frac{1 - \pi_a}{\pi_a} = T_a,$$

<sup>†</sup>*Discussants:* Axel Leijonhufvud, University of California-Los Angeles; Mark J. Machina, University of California-San Diego.

\*Member, 1984-85, The Institute for Advanced Study, Princeton, NJ 08540; and Department of Economics, Brigham Young University.

where  $R_a$  = the "right" circumstances for which selecting action  $a$  will either maintain or raise performance compared to that achievable when agents select actions only from  $A - \{a\}$ ,  $W_a$  = the "wrong" circumstances for which selecting action  $a$  will lower performance compared to that achievable when agents select actions only from  $A - \{a\}$ ,  $l_a$  = the "loss" in performance (compared to selecting only from  $A - \{a\}$ ) if action  $a$  is selected under the wrong conditions  $W_a$ ,  $g_a$  = the "gain" in performance (compared to selecting only from  $A - \{a\}$ ) if action  $a$  is selected under the right conditions  $R_a$ , and  $r_a = p(a|R_a)$  and  $w_a = p(a|W_a)$ ;  $\pi_a = p(R_a)$  and  $1 - \pi_a = p(W_a)$ .

The ratio  $r_a/w_a$  measures the "reliability" of selecting action  $a$  under the right instead of the wrong conditions.  $T_a$  measures the minimum required reliability or "tolerance limit" that must be satisfied before allowing flexibility to select action  $a$  will benefit an agent. Note that this condition becomes interesting only when the ratio  $r_a/w_a$  is finite, so that  $r_a/w_a > T_a$  may or may not be satisfied. Note also that if  $r_a/w_a$  is bounded and  $l_a/g_a$  is positive, then  $r_a/w_a > T_a$  will not hold for a sufficiently small but still positive probability of favorable circumstances,  $\pi_a > 0$ .

### II. Conventional Choice Theory is a Special Case

Let us briefly compare reliability theory with the conventional Bayesian decision framework (see my 1985b paper for further discussion). Let  $\gamma(a; x)$  represent the set of consequences resulting from action  $a \in A$  when a message  $x \in X$  is received; where consequences refer to the statistical likelihood of potential outcomes, and actions may

likewise represent randomized strategies over a set of more basic actions. In addition, let  $V(\gamma)$  represent a value function (such as traditional expected utility) which measures the performance derived from different consequences. Conventional decision theory assumes agents behave according to a maximizing decision rule,  $B^*(x)$ , such that for each message  $x$  received  $a = B^*(x)$  if and only if  $V(\gamma(a; x)) \geq V(\gamma(b; x))$  for any other  $b \in A$ .

Now think of this in terms of the probabilities  $r_a$  and  $w_a$ , where  $M_a \subset X$  denotes those messages  $x \in X$  for which the consequences resulting from action  $a$  are maximal as just defined. If  $x \in M_a$ , then  $x$  must also be in  $R_a$  since the consequences from selecting  $a$  are at least as preferred as those resulting from any other action. Conversely, if  $x \notin M_a$ , then some other action will outperform action  $a$ , and thus would be selected by  $B^*(x)$ . Hence, if action  $a$  were selected when  $x \notin M_a$  then performance would drop compared to that achievable with  $B^*(x)$  restricted to  $A - \{a\}$ . The above two implications together imply  $x \in M_a$  if and only if  $x \in R_a$ ; which in turn implies  $M_a = R_a$  and  $X - M_a = W_a$  for any  $a \in A$ . Therefore, since  $B^*(x)$  selects actions if and only if their consequences are maximal we must have  $r_a = p(a = B^*(x) | R_a) = 1$  and  $w_a = p(a = B^*(x) | W_a) = 0$  for all  $a \in A$ .

The above result implies that  $0 < w_a$  and  $r_a < 1$  cannot hold for any action so long as  $B^*(x)$  is used. Yet, as already mentioned, the condition  $r_a/w_a > T_a$  becomes interesting only when the ratio  $r_a/w_a$  is bounded, which is impossible if  $r_a = 1$  and  $w_a = 0$  for all  $a$ . This can also be understood in terms of the probability of Type I and Type II errors (meaning failure to select an action  $a$  when doing so is optimal and still selecting it when doing so is not optimal), denoted  $t_a^1$  and  $t_a^2$ , respectively. Note  $r_a = 1 - t_a^1$  and  $w_a = t_a^2$ , so that  $B^*(x)$  implies  $t_a^1 = 0 = t_a^2$  for all  $a$ . Conventional theory thus represents the limiting case where agents perfectly respond to information.

However, more important than this conclusion is the analytical shift from decision rules like  $B^*(x)$  to the information-response probabilities  $r_a$  and  $w_a$  derived from them (hereafter called "behavior probabilities"). (For further analysis and experiments about

the  $r_a$ ,  $w_a$  (and  $\pi_a$ ) probabilities, as distinct from subjective Bayesian Probabilities, see my 1985a article). Previous inquiry (most notably by Herbert Simon; for a recent summary, see his 1983 study, pp., 12-23) has never been able to identify a modeling alternative of similar generality and rigor to neoclassical choice theory. In contrast, representing optimal decision rules in terms of the behavior probabilities  $r_a$  and  $w_a$  enables one naturally to see that they are at the boundary of a more general domain. Moreover, with these probabilities we can use research from a number of key fields (including major portions of existing risk and statistical theory) to analyze how they change under different conditions (thereby formally modeling behavior away from the boundary defined by traditional maximization).

### III. The General Validity of the Reliability Condition

The reliability condition was only intuitively developed in the Origin paper (for example, no explicit consideration of the size and topology of action, information, and environmental state spaces was given). In fact, the condition is valid under quite general conditions comparable to the most rigorous treatments of conventional choice theory. Let  $\Delta^i(\gamma, \gamma')$  represent a value function that measures the *difference* in performance from consequences  $\gamma$  and  $\gamma'$ , where  $i$  refers to the type of value function used. If  $\Delta^i$  is axiomatized with certain properties (for example, the "independence" axiom) then it will be separable into  $V(\gamma) - V(\gamma')$ , where  $V$  measures the traditional expected utility of different consequences. However, if the more recent "non-expected utility" theories of Machina, Chew, Fishburn, Loomes and Sugden, etc. (see part 5 of Mark Machina, 1983) are used, then  $\Delta^i$  may not be separable into a single  $V$  function.

Let  $\gamma^B$  denote the consequences produced when agents select actions only from a set  $B \subset A$ . It can be shown for any of the  $\Delta^i$  functions mentioned above (see my 1984 paper), that  $\Delta^i(\gamma^A, \gamma^{A-(a)}) > 0$  if and only if  $r_a/w_a > T_a$  is satisfied. Thus, the basic form of the reliability condition holds for any of the  $\Delta^i$  functions (where  $\Delta^i$  affects how the  $l_a$

and  $g_a$  components are measured). Note, however, that we may still have a bounded  $r_a/w_a$  ratio, so that using a  $\Delta^i$  function does not imply agents are able to maximize according to  $\Delta^i$ . That is, *using value functions like  $\Delta^i$  does not imply agents always behave so as to maximize the "posterior" attainable performance conditional on each message received.* Consequently, the reliability condition provides a way of modeling behavior (with the help of value functions like  $\Delta^i$  and behavior probabilities  $r_a, w_a$ ) which no longer requires the maximizing postulate to be used.

#### IV. Formalizing the Relationship between Uncertainty and Predictable Behavior

Next consider how to formally characterize the relationship between uncertainty and predictable behavior. We can precisely measure behavioral predictability with entropy concepts used in statistical mechanics and information-cybernetics' theory. Let  $h_a$  be the probability of selecting an action,  $h_a = p(a)$ . Then the behavioral entropy of potentially selected actions in  $A$  is,  $E^B = -\sum h_a \log h_a$ , for  $a \in A$ . The entropy measure  $E^B$  increases as agents might select more actions, but no single action is frequently chosen (so that higher  $E^B$  means behavior is more difficult to predict; see Claude Shannon and Warren Weaver, 1963, for further analysis of entropy measures).

Next let  $\rho$  denote the set of  $r_a/w_a$  ratios for choosable actions in  $A$  (i.e.,  $\rho = \{r_a/w_a | a \in A\}$ ). The set  $\rho$  describes an agent's reliability in responding to information about when to select particular actions. The limiting case where agents are perfectly reliable is denoted  $\rho^\infty$ , meaning the  $r_a/w_a$  ratios are infinite.  $\rho$  is said to be *bounded* if the reliability ratios of each action do not exceed some finite upper limit  $K$  (i.e.,  $r_a/w_a \leq K$  for all  $a$ ). In the case of  $\rho^\infty$  agents still face "risk" due to imperfect information, but no additional uncertainty is involved. The term "uncertainty" is thus reserved for the case when  $\rho$  is bounded. In addition, let  $\rho^1$  represent the other extreme case where agents are completely unable to distinguish right from wrong conditions for selecting different actions (so that they are equally likely to select actions under either  $R_a$  or  $W_a$ ). Thus,

$\rho^1$  means  $r_a/w_a = 1$  for all  $a$ . The reliability sets  $\rho$  describe a range of uncertainty possibilities, beginning with  $\rho^1$  at one extreme and proceeding through intermediate cases where  $\rho$  is still bounded,<sup>1</sup> finally limiting on  $\rho^\infty$  where only imperfect information remains.

One can prove (see my 1985b paper for more discussion) that  $E^B(\rho)$  approaches zero as  $\rho \rightarrow \rho^1$ ; and conversely that  $E^B(\rho)$  increases beyond any finite bound as  $\rho \rightarrow \rho^\infty$ . The latter result implies that it is the boundedness of  $\rho$  (i.e., the presence of uncertainty) that limits agents' behavioral entropy. We can thus regard uncertainty as the basic source of predictable behavior in the following sense: *recurrent patterns in behavior noticed by an observer (because  $E^B(\rho)$  is bounded) would not have arisen in the first place without uncertainty affecting agents' decisions.*

#### V. Decomposing Reliability into Two Major Stages

Now extend the reliability concepts discussed above by applying them to the overall relationship between the environment and agents' behavior. This can be split into many substages, but only two major ones are discussed here: namely, from the environment to observed information about its true state; and from such information to finally executing agents' behavior.

Previous discussion focused on the second stage, where  $r_a/w_a$  measured the reliability of responding to the right and wrong information,  $R_a$  and  $W_a$ . We can also talk about the right and wrong environmental states for selecting different actions (i.e., those states where selecting action  $a$  would raise or lower performance compared to that achievable when only selecting from  $A - \{a\}$ ). In order to indicate this distinction, let us explicitly superscript  $R_a$  and  $W_a$  with  $S$  when defined in terms of environmental states and similarly with  $X$  when referring to information about the environment. The reliability of agents' behavior in responding to informa-

<sup>1</sup> Bounded reliability sets  $\rho$  may also be understood as a way of formally defining and quantifying Simon's idea of "bounded rationality."

tion is then denoted (for each action  $a$ ) as  $\rho_a^B = r_a^B / w_a^B$ , where  $r_a^B = p(a = B(x) | R_a^X)$  and  $w_a^B = p(a = B(x) | W_a^X)$ . Separate from agents' ability to use information, the reliability of information about when to select a particular action  $a$  is represented by  $\rho_a^X = r_a^X / w_a^X$ , where  $r_a^X = p(R_a^X | R_a^S)$  and  $w_a^X = p(R_a^X | W_a^S)$ . The overall reliability over both stages (given by the ratio  $\rho_a^{XB} = r_a^{XB} / w_a^{XB}$ ) can be shown to have the following general form,

$$(2) \quad \frac{r_a^{XB}}{w_a^{XB}} = \frac{r_a^X(\rho_a^B - 1) + 1}{w_a^X(\rho_a^B - 1) + 1}.$$

Conventional theory represents the limiting case where agents perfectly use information (i.e.,  $\rho_a^B = \infty$  for all  $a$ ); so that  $\rho_a^{XB}$  reduces to  $\rho_a^X = r_a^X / w_a^X$ . This implies agents' overall reliability depends only on the information available to them. On the other hand, the structure of (2) enables one to explicitly analyze the interplay between imperfect information and imperfect response to information. We can thereby retain the essential elements of Bayesian theory, yet enter a previously uncharted domain of inquiry (one that has seemed beyond the limits of formal analysis).<sup>2</sup> In general, note that  $\rho_a^{XB}$  necessarily drops below  $\rho_a^X$  when  $\rho_a^B$  is bounded, converging on 1 as  $\rho_a^B \rightarrow 1$ . The latter must happen no matter how reliable information might be (i.e., no matter how close  $r_a^X$  and  $w_a^X$  approach 1 and 0, respectively).

#### VI. The Complexity of Information: A Basic Tradeoff

Results in cybernetics and information theory imply that in order to fully describe the environment, an information source must have an intrinsic entropy (denoted  $E^X = -\sum h_x \log h_x$ , where  $h_x = p(x)$ ) at least as great as that of the environment. This means that  $E^X$  is a positive function of  $\rho_a^X$ , denoted  $E^X(\rho_a^X)$ . Next combine this with another

principle that agents have greater difficulty in perceiving and interpreting information as its entropy increases. This principle has been extensively tested and confirmed in experimental psychology (see, for example, Wendell Garner 1962, ch. 3), and formally means  $\rho_a^B$  is a negative function of  $E^X$ , denoted  $\rho_a^B(E^X)$ . By combining both of these relationships into  $\rho_a^B(E^X(\rho_a^X))$  and substituting into  $\rho_a^{XB}$  we thus derive the following basic tradeoff: as information more accurately describes the environment its entropy increases and thereby reduces agents' reliability in responding to it. This is implied irrespective of whether there are any costs of obtaining information (as modeled in conventional "search theory").

From this one can prove that agents may be in the immediate presence of a number of *costless* information sources, yet only respond to the less reliable information which thereby has less complexity to interpret. The latter result (as well as the information-complexity tradeoff itself) is one of a number of broadly applicable behavioral principles that can be rigorously derived from reliability formulas like (2) above. In addition, such formulas enable one to harness a large body of analysis already developed in cybernetics and information theory (but which has found little use in conventional decision theory).

#### VII. Brief Applications

I conclude by sketching some applications of the information-complexity tradeoff, first for biology applications and then human applications.

(a) The above implication about ignoring costless information will be more noticeable as agents become less able to reliably interpret increasingly complex messages (so that  $\rho_a^B$  falls more quickly as  $E^X$  increases). A striking class of examples of this are known as *releasing mechanisms* in animal behavior. The following describes a well-known case.

Niko Tinbergen...studied fighting between male stickleback fish.... In the spring the throat and belly of the males become intensely red. It seemed probable, therefore, that the red color was

<sup>2</sup>See the statements by Kenneth Arrow, Robert Lucas, and John Hey at the start of my 1985a article.

an important stimulus. The investigators presented their subjects with a series of models, some quite like actual male sticklebacks except that they lacked the red coloration, and some showing little resemblance to actual sticklebacks except that they were red on the lower surface. The male fish attacked the red-bellied models, despite their unfishlike appearance, much more vigorously than they did the fish-like ones that lacked red. Surely the sticklebacks could see the other characteristics of the models, but they reacted essentially only to the releasing stimuli from the red belly.

[William Keeton, 1976, p. 504]

(b) Formula (2) implies that if  $\rho_a^B$  is bounded then there exists a finite upper bound in behavioral entropy (denoted  $\hat{E}^B$ ) beyond which the reliability condition cannot hold for all actions in an agent's repertoire. If  $\hat{E}^B$  is less than the entropy of environmental states (denoted  $E^S$ ), then it can also be shown that  $\hat{E}^B$  will drop for a sufficient increase in  $E^S$  (i.e., when the environment becomes sufficiently more unpredictable). On the other hand, one can show agents must display more entropy in their behavior in order to maintain any given level of performance in the face of a more unpredictable environment (i.e., higher  $E^S$  requires a higher minimum behavioral entropy, denoted  $\tilde{E}^B$ , in order to maintain a given performance level; see W. Ross Ashby, 1963, ch. 11). The latter can be summarized by a positive relationship  $\tilde{E}^B(E^S)$ . Thus we have another basic tradeoff whereby increasing  $E^S$  will eventually raise  $\tilde{E}^B(E^S)$  above  $\hat{E}^B$ .

Next suppose agents must achieve some minimum performance level in order to maintain competitive survival in the environment. The last conclusion then implies agents will eventually drop out of the environment as its entropy increases. However, we can also use this result in the converse sense by starting with a given  $\hat{E}^B$  and using  $\tilde{E}^B(E^S)$  to determine an upper limit on  $E^S$  consistent with the survival of particular agents (thereby permitting such agents to evolve in the first place). Those environments (or portions of a larger environment) with small enough  $E^S$

for certain agents to evolve can then be defined as the *niches* of such agents. Note how the latter characterization follows directly from reliability principles derived from (2) above.

(c) From this point a number of related features in ecological structure can be pursued. One possibility is to investigate the kinds of competitive interactions between species that would either tightly constrain or quickly increase the environmental entropy mutually faced by the particular species involved (thereby either ensuring or preventing the survival condition  $\tilde{E}^B(E^S) \leq \hat{E}^B$  from being satisfied). Answering this question will enable specific predictions about which kind of niche structures are likely to evolve and which are not. For example, suppose competition between species within a given geographical region quickly increases the environmental entropy they mutually create for themselves as they become sufficiently similar in morphology or other ecologically relevant dimensions. If this is the case, then spatially overlapping niche structures between ecologically similar species will be very unlikely to evolve. This is the dominant pattern evidenced in nonhuman biology.

Now I briefly turn to human agents competing in exchange environments.

(d) Similar to the above examples one can ask what sorts of exchange environments would quickly raise  $\tilde{E}^B(E^S)$  relative to  $\hat{E}^B$  for the agents involved. This might refer to particular markets, or to interdependencies across a number of markets. Answers to these questions will enable predictions about the kinds of intra- and intermarket structures likely to evolve (for example, about where "flex" vs. "fix"-price markets will tend to be located in a large industrial economy with numerous cross connections between producer, consumer, and financial markets). Such predictions will in part depend on how different institutional features affect the complexity of price and quantity signals likely to be transmitted within and between specific markets.

(e) Another possibility involves the complexity of messages transmitted between agents competing in game theory contexts. Conventional models have tended to char-

acterize increasingly sophisticated "optimal" strategies. However, if agents' reliability  $\rho_a^B$  in responding to information decreases with the uncertainty of potentially transmitted messages,  $E^X$ , then noticeably different solution concepts may result. For example, rigid strategies that allow response only to relatively simple messages (such as tit for tat; see Robert Axelrod, 1984) may come to dominate over more sophisticated strategies (that may require agents to respond to messages which they cannot reliably interpret).

(f) Finally, consider briefly the effects of inflation. Again using formula (2) one can show there is a maximum entropy of information (denoted  $\hat{E}^X$ ) beyond which trying to use more complex information will reduce agents' overall reliability  $\rho_a^{XB}$  (thereby reducing their performance). In addition, if we fix  $E^X$  at any given level, then its reliability  $\rho_a^X$  will drop as the environment's entropy  $E^S$  increases. Assume also  $E^S$  exceeds  $\hat{E}^X$ , so that agents are initially using information with entropy  $\hat{E}^X$ . Then suppose something happens to the environment that increases  $E^S$ . The above two principles imply agents' performance must drop as  $E^S$  increases (i.e., greater entropy of information is necessary to maintain its reliability as  $E^S$  increases, yet trying to use more subtle information with  $E^X > \hat{E}^X$  will only further reduce agents' overall reliability; moreover, those information sources with  $E^X \leq \hat{E}^X$  are all less reliable than before). Agents may be able to recoup part of their losses by responding appropriately to information with smaller  $E^X$ , but they can never fully restore their initial performance.

Now apply the above analysis to the case where inflation rises, but in a manner that also increases the entropy of price and quantity relationships in the economy. If this happens, agents' performance achieved from market participation will unavoidably drop. We thus may have a social cost to rising inflation that is not readily apparent with

conventional macro models (which often view inflation as fully "anticipated," or "neutral," or dealt with via "indexing" and other contractual adjustments, etc.; see Axel Leijonhufvud, 1981, chs. 9 and 10).

# Individual Rationality, Market Rationality, and Value Estimation

By PETER KNEZ, VERNON L. SMITH, AND ARLINGTON W. WILLIAMS\*

Direct experimental tests of expected utility theory (*EUT*), in which subjects are asked to choose among alternative gambles, or to make judgements as to their willingness to pay (*WTP*), and/or willingness to accept (*WTA*) payment for a gamble, have not been kind to *EUT*. As noted in the survey by Paul Slovic and Sarah Lichtenstein (1983), the results of these interrogations are remarkably consistent in a wide variety of contexts and are robust under examinations designed to determine the effect of monetary incentives, experience, and other factors that might have accounted for the discrepancy between subject responses and the predictions of *EUT*. On the other hand, experimental studies of individual and market behavior based upon *EUT* models of market decision making have yielded results showing high consistency with the predictions of these models (see the references in Smith, 1985). Are individual revealed preferences in some market contexts more likely to be "rational" (consistent with *EUT*) than individual responses to choices among alternative prospects?

Several studies designed to solicit *WTP* and *WTA* responses for a variety of goods have found a wide disparity between the "buying price" and "selling price" measures of individual value (see the study and the citations therein by Jack Knetsch and J. A. Sinden, 1984; hereafter K-S). Values of *WTA* obtained in this way are frequently an order of magnitude greater than values of *WTP* although theoretically *WTP* and *WTA*

"should" differ by no more than a presumed "small" income effect. These results should not be dismissed by economists on the grounds of poor subject motivation because the experiments include some (see those in K-S) that have carefully introduced actual monetary payments and cash compensations and have not relied on hypothetical choices.

These results are explained by K-S (and by most of the authors of such studies) in terms of the Daniel Kahneman and Amos Tversky (1982) "framing" paradigm in which people reveal that they are less willing to spend wealth which they consider to be part of their endowment than wealth not so considered. We would emphasize that such behavior is "irrational" only in the narrow sense of *EUT* as a behavioral hypothesis which may not only be a poor predictor of individual choice, but may not be a satisfactory guide to action. For example, the differential treatment of wealth that has become part of one's endowment may have important survival value which is imprinted in decision behavior. However, K-S (p. 508, fn. 3) report one, perhaps significant, experiment in which they do not get the usual *WTA-WTP* disparity. In this experiment, cash payments and offers for a lunch made to respondents entering an office cafeteria showed a much smaller, statistically insignificant, disparity. In this case, the respondents were about to participate in a familiar market for the commodity being evaluated.

On this same theme an important new study by Don Coursey et al. (1984) uses a repetitive series of Vickrey (second price) auctions to determine market *WTA* and *WTP* prices for entitlements to an unfamiliar item, which they compare with hypothetical measures of *WTA* and *WTP*. They find that although individual bids in the first of a sequence of Vickrey auctions show a large *WTA-WTP* disparity, ending bids, after a

\*Graduate Student in Finance, University of Pennsylvania, Philadelphia, PA 19104; Professor of Economics, University of Arizona, Tucson, AZ 85721; Assistant Professor of Economics, Indiana University, Bloomington, IN 47401. Research support from the National Science Foundation is gratefully acknowledged.

series of auctions, yield no such disparity. Their interpretation is that market-like learning experience yields results that are not inconsistent with the "rational" economic model. Since the motivation for such models is to articulate a theory of market behavior, we would argue that the Coursey et al. work raises fundamental questions as to the appropriate context, in which tests of the observable implications of economic theory are to be carried out. In this emphasis we are not denying the reality of what Kahneman and Tversky have called "framing effects." Such effects are identifiable both in the hypothetical and the reward motivated contexts in which they have been measured. What we are questioning is the uncritical *interpretation* of the implications of this research for the theory of markets (Kenneth Arrow, 1982). According to this interpretation, the results of direct studies showing that individual participants are subject to "framing" effects implies that markets are inefficient. We think this interpretation is incorrect (see Smith) for two reasons.

1) It confuses individual "rationality," in the sense of *EUT*, with market rationality, in the sense of allocative efficiency. Market efficiency is a proposition about allocations given demand behavior, while *EUT* leads to propositions about "rational" demand behavior. Thus *EUT* could have very poor predictive power, but given this *EUT*-inconsistent demand environment, markets might be highly efficient. Also, an essential feature of markets is that price is determined by the marginal traders, and the presence of non-marginal traders who are *EUT* irrational does not imply that market prices are *EUT* irrational.

2) Direct studies of framing have concentrated on inconsistencies in individual responses to questionnaires, or in one-shot buying and selling decisions in which individuals do not have the opportunity to participate in an ongoing market. If individuals modify their opinions and their decisions in the light of this experience, these effects will not be reflected in the instruments that have been used in framing studies. We would argue that although such studies have relevance to measuring people's

preference attitudes, they provide no basis for extrapolation to behavior in markets. Most (but not all) experimental markets show some learning effects over time with equilibrium behavior quite different from start-up behavior.

In this paper we report the results of two series of experiments designed to address two research questions: 1) if we ask subjects *WTP* and *WTA* questions concerning a security that yields a random dividend from a known probability distribution, and that will be traded in a market, do these responses, even if inconsistent with *EUT*, provide "good" predictors of the mean market price generated by trading among these same subjects? By a good predictor, we mean that it does at least as well in predicting the mean market price as does the rational expectations equilibrium (*REE*) theory of such a market. 2) If trading is repeated over several consecutive market periods, and we apply the *WTA-WTP* questionnaire instrument between each of these trading periods, do we observe any trend in effect on subject responses in this context?

### I. Experimental Design and Results, Series I

The first group of experiments on which we report were not designed to study *WTP* and *WTA*. These experiments were designed to study the efficient markets hypothesis (or *REE*) in the context of asset trading under double auction contracting rules, where an asset's value is derived from a random dividend distribution (for a more complete discussion, see Smith et al., 1985). In these experiments, nine (or twelve) subjects participate in a sequence of fifteen consecutive trading periods for an asset whose dividend probability distribution is common knowledge. At the end of each trading period, all shares receive the dividend realized for that period. In period 1, each share represents a prospect that will yield fifteen realizations from the given distribution; in period 2 a share can claim fourteen remaining realizations; and so on until the final period when only one realization remains. Each subject begins period 1 with an endowment of cash and securities. The expected (dividend) value

of a share in period 1 is \$3.60 (15 periods times the expected dividend per period, \$0.24), or, in some designs, \$2.40. This is the *REE* price based on expected value as the "intrinsic worth" of a share (the *REE* price adjusted for risk-averse or risk-preferring behavior may be below or above this expected dividend value). Each subject ends the 15-period experiment with his or her initial cash endowment plus the sum of all dividend realizations plus (minus) any net capital gains (losses) from trading shares during the fifteen periods.

After completing an initial series of twelve experiments of this type, we applied a *WTA-WTP* instrument in our subsequent fourteen experiments (Series I). After each subject had completed the asset market instructions and been informed of the dividend structure and of his or her initial endowment, but before the opening of the first trading period, the following two questions were administered: 1) Given your endowment of \$ \_\_\_\_\_ cash (i.e., working capital) and \_\_\_\_\_ asset units, what would be the minimum price you would be willing to accept in order to sell one unit of your inventory in the trading period about to begin? \_\_\_\_\_. 2) Given your endowment of \$ \_\_\_\_\_ cash (i.e., working capital) and \_\_\_\_\_ asset units, what would be the maximum price that you would be willing to pay in order to buy one unit of this asset in the trading period about to begin? \_\_\_\_\_.

The results of our fourteen Series I experiments are shown in Table 1 which lists the buyer and seller surpluses and the predicted market price ( $P_w$ ) based on the *WTA-WTP* interrogations, as well as the actual mean transaction price ( $\bar{P}$ ) for all trades in period 1. Price  $P_w$  equates supply and demand, where supply is the *WTA* responses ordered from lowest to highest, and demand is the *WTP* responses ordered from highest to lowest. Our results are summarized as follows.

1) We first asked if the mean price deviations in period 1,  $p_r = \bar{P} - P_r$  (measured in deviations from the normalizing *REE* price,  $P_r$ ) differ between the prior series of twelve experiments that did not apply the *WTA-WTP* interrogation, and the fourteen Series I experiments that did. Since these sample

TABLE 1—SERIES I RESULTS

Exp.	Surplus Seller : Buyer	<i>WTA, WTP</i> Price	Mean Price
116	2.9:11.1	1.47	1.53
117 <sup>a</sup>	2.1: 8.8	1.00	1.74
118	4.4: 4.0	1.90	2.10
119 <sup>b</sup>	0.5: 2.0	3.00	5.44
125 <sup>b</sup>	2.4: 2.3	2.00	2.55
128 <sup>b</sup>	3.1: 1.1	1.62	1.85
139 <sup>b</sup>	0.6: 4.1	0.60	0.42
141 <sup>a</sup>	4.3:12.3	1.62	2.32
142 <sup>b</sup>	5.2:11.9	2.32	3.78
143 <sup>b</sup>	8.1: 2.9	3.59	3.42
146 <sup>b</sup>	1.4:10.2	1.00	2.67
148 <sup>b</sup>	6.1: 2.8	2.62	3.55
149 <sup>b</sup>	3.8: 2.7	2.75	3.40
150 <sup>b</sup>	2.5: 0.4	3.50	3.40

Note: Exp. denotes experiment.

<sup>a</sup>Denotes  $P_r = 2.40$ , otherwise  $P_r = 3.60$ .

<sup>b</sup>Denotes experienced subjects.

mean deviations are \$0.46 and \$0.70, respectively, and their difference is not statistically significant ( $t = 0.56$ ), interrogation appears not to affect prices.

2) Buyers' surplus tends to exceed sellers' surplus, which implies that there is more diversity among intramarginal limit buy prices than among corresponding limit sell prices. However, this difference is not significant ( $t(26) = 1.6$ ). Since *WTA* and *WTP* reflect expectations about future price increases and the concomitant capital gains, it would appear that such expectations varied considerably among subject trader groups.

3) Comparing the predictive error of the *WTA-WTP* equilibrium price,  $p_w = \bar{P} - P_w$ , with that of the *REE* price,  $p_r = \bar{P} - P_r$ , we reject the null hypothesis that  $\sigma_w^2 = \sigma_r^2$  in favor of  $\sigma_w^2 < \sigma_r^2$  ( $F = 2.45$ ). Hence the *WTA-WTP* data do much better in predicting the mean trading price than the widely touted "intrinsic value" or *REE* theory of stock prices.

4) In each experiment we have complete data on all of the bids and/or offers submitted by each subject, allowing us to compare actual bids with  $WTP_i$  and actual offers with  $WTA_i$ . Examining these data we find that the lowest offer made was below the stated  $WTA_i$  for 14 percent of the subjects, while the highest bid entered was above the

stated  $WTP_i$  for 46 percent of the subjects. We conjectured that buyers were more willing to abandon their  $WTP$ s because they sensed a possible rising market in period 1 and were going for capital gains. Most of the markets would subsequently confirm this prediction (see Smith et al.).

## II. Experimental Design and Results, Series II

In a Series I experiment, the first market period requires evaluating a complicated compound gamble. Furthermore, since it is the first of a 15-period sequence of trading periods, it may be quite important in yielding expectations information for each agent. Hence a subject with well articulated  $WTA$  and  $WTP$  attitudes based only on dividend information, endowment, and "thinking about it," may alter those attitudes drastically upon observing the first few trades that reveal something about the behavior of others. Consequently, our second series (II) of three experiments each consisted of four or six single trading periods for an asset in which all subject endowments were *reinitialized* at the beginning of each period of trading. This pure replication design controls on any first-period trading effects due to capital gains expectations across periods (but not, of course, within a period). In these experiments a single draw at the end of one period of trading is made from a binary probability dividend distribution ( $p_1, d_1; p_2, d_2$ ) = ( $\frac{1}{2}, \$0.50; \frac{1}{2}, 2.00$ ), with expected value \$1.25. If we define  $E$  = (cash, shares) as the endowment vector, there are three agent classes,  $E_1 = (\$4.50, 1)$ ,  $E_2 = (\$3.25, 2)$ , and  $E_3 = (\$2.00, 3)$  with three subjects in each class comprising a nine-trader market. Hence the expected value of each agent's endowment is \$5.75 in each of the independently initialized trading periods in an experiment. Except for the effects of learning, each trading period is a pure replication of the market for a single binary gamble. In this environment, we administer the above questionnaire.

The results of our three Series II experiments consisting of 16 independent single-period markets, each preceded by a  $WTA$ - $WTP$  interrogation, are shown in Table 2. Our results are summarized as follows.

TABLE 2—SERIES II RESULTS

Exp.: Period	Surplus Seller: Buyer	$WTA, WTP$ Price	Mean Price
129:1	1.9:0.9	1.25	1.66
2	1.3:0.9	1.25	1.39
3	0.9:0.5	1.62	1.60
4	1.2:0.3	1.50	1.41
133:1	2.2:2.9	1.25	1.30
2	2.0:0.2	1.42	1.51
3	0.4:0.3	1.47	1.52
4	0.5:0.2	1.50	1.58
5	1.0:0.3	1.50	1.51
6	0.2:0.0	1.50	1.58
137:1	1.9:3.1	1.12	1.43
2	1.2:0.5	1.50	1.49
3	1.0:0.2	1.40	1.40
4	0.5:0.2	1.40	1.26
5	0.7:0.4	1.30	1.18
6	0.3:0.5	1.20	1.21

Note:  $P_r = 1.25$  in all experiments.

1) The  $WTA$ - $WTP$  schedules for both the Series I and II experiments typically reveal frequent inconsistencies with  $EUT$ . For example, in period 1 of experiment 133, subjects 3 and 7 report  $WTP$ s that equal or exceed the maximum possible payoff (\$2). However, these violations of simple dominance are not repeated. In spite of the  $EUT$  inconsistencies, the period 1 market-clearing price of \$1.25 can hardly be classified as irrational.

2) Comparing Tables 1 and 2, both seller and buyer surpluses tend to be smaller in Series II (period 1) than their counterparts in Series I. This is consistent with the expectation that moving from a compound to a single one-draw gamble will reduce the diversity in both the  $WTA$  and  $WTP$  measures of individual value. In Table 2, sellers' surplus is larger than buyers' surplus in all but three trading periods.

3) In ten of sixteen periods  $P_w$  is a better predictor of  $\bar{P}$  than  $P_r$ , but the repeat trials with the same subject group in each experiment yields a sample that is too small (three independent sets of observations) for a meaningful test.

4) If in each trading period we compare  $WTA_i$  with actual offers and  $WTP_i$  with actual bids for each subject, we find that for 34

percent of the subjects the lowest offer made was below their stated  $WTA_i$ , and for 47 percent the highest bid was above their stated  $WTP_i$ . The abandon with which subjects violate their own  $WTA$ - $WTP$  responses suggests that the latter may serve only as a pretrade bargaining objective from which there is frequent deviation.

5) Standard (risk-averse) theory suggests that for any  $i$ ,  $WTA_i$  will equal or exceed  $WTP_i$ . We counted the number of individuals who violated this inequality in their period-by-period  $WTA$ - $WTP$  responses. The number of violations in successive trading periods of each Series II experiment are as follows: Exp. 129: 0,0,0,0; Exp. 133: 3,2,1,2,3,0; Exp. 137: 5,2,1,0,2,1. By this measure of "rationality," it appears that replication of the interrogation followed by market experience sequence tends to reduce the incidence of  $EUT$  inconsistent responses, with most of the reduction occurring in period 2.

### III. Conclusions

The following conclusions appear to be justified by the above experiments: 1) The  $WTA$ - $WTP$  interrogation itself does not have a significant effect on the subsequent observed mean contract price of an asset. 2) In Series I, based on the  $WTA$ - $WTP$  data, buyer's and seller's surplus do not differ significantly. 3) Subjects often submit actual offers below their stated  $WTAs$ , and/or bids above their stated  $WTPs$  (14 to 47 percent of the responses), suggesting perhaps as L. J. Savage once said, "It is difficult to be honest with one's self about prices generally" (1962, p. 165). 4) Although these  $WTA$ - $WTP$  responses are frequently abandoned by subjects, the equilibrium predicted prices,  $P_w$ , that result are not bad predictors of the mean observed contract prices, in the sense that  $P_w$  is closer to the mean price than the "intrinsic" value  $REE$  price,  $P_r$ . 5) Over time in Series II there is a considerable decrease in subject violation of the risk-averse rationality prediction  $WTA \geq WTP$ .

Extensive studies of the consumption-leisure revealed choice behavior of mice, rats, monkeys, pigeons, and people in repeat

purchase environments (Raymond Battalio et al., 1981, p. 623) yield steady-state results consistent with the Slutsky-Hicks model of maximizing behavior. For the animal studies there is no presumption of cognitive calculating choice, yet this presumption is *implicit* in tests of  $EUT$  based on subject responses to one-shot choices among gambles and/or word problems. We do not deny that  $EUT$  is in trouble standing as a clearly nonfalsified theory of decision making under uncertainty, but we would urge suspension of scientific judgement until this evidence has been further examined in repetitive market-like environments. In any case, there is no justification for the normative and judgemental conclusion that  $EUT$  violations imply that either individuals are incompetent or markets are inefficient. What may be in doubt is  $EUT$  as an attempt to give formal meaning to the concept of rationality.

# Knowledge, Uncertainty, and Behavior

By KEITH D. WILDE, ALLEN D. LeBARON, AND L. DWIGHT ISRAELSEN\*

Our paper reports the initial results of a multidisciplinary evaluation of Ronald Heiner's (1983) thesis about the sources of predictable behavior.<sup>1</sup> A selection of ideas and examples that illuminate or reinforce Heiner's argument is presented here. We also record consensus views on some implications of Heiner's behavioral model as we understand it.

## I. Knowledge/Cognition/Rationality

Our approach to Heiner's thesis is shaped by interest in the processes of cognition, other sources of human behavior, and the implications of knowledge growth for man and the biosphere. His work is illustrative of uncomfortable implications and problems created by the explosive growth of knowledge in the modern era. Many of us work inside large organizations where our responsibility is to promote a kind of intelligent, flexible, and adaptive behavior that Heiner says must emerge as a condition of increased organizational complexity.

From that perspective we were attracted to two of Heiner's major points about human behavior: first, that people cannot cope with all the information available; second,

that knowledge creates uncertainty. We affirm these statements, but are uncertain of Heiner's view on how increasingly complex, viable, social structures evolve. One of our initial impressions was that he attributes consciousness to subhuman forms of life, even though his article claimed to be imputing only sensory or perceptual powers, not cognitive or conceptual ones.

There remains nonetheless an impression that some kind of economic or biological (i.e., success or survival) rationality is the outcome of "successful" behavior. If Heiner is not attributing consciousness, he is at least observing development of behaviors that permit survival. Economic reasoning might call such behaviors "rational" from a retrospective viewpoint. As organisms and organizations become more complex, rationality of this kind seems to require more and more nearly conscious effort. Heiner calls optimization a special case occurring when uncertainty (the *C-D* gap) approaches zero. Optimization would be rational and also conscious, we infer, since it implies deliberate decision taking. At lower levels of certainty, rule-governed behavior prevails. The choice of rules and of behavior within them could be rational without full consciousness. This we infer is Heiner's meaning and we do not necessarily disagree (as some of our examples will demonstrate).

We believe an implication of Heiner's work is that rational (i.e., enabling survival or success) behavior requires increasing degrees of conscious effort. We are given to understand that he is aiming at a more general theory of human behavior, one that subsumes optimization, or economic rationality, as special cases. He aims at illumination rather than revolution he says, but we think the implications are revolutionary. If he is not preserving economic man, then he is destroying the Invisible Hand.

From the anthropological perspective, Heiner has situated economic debate squarely into the mainstream of Continental intellec-

Miles, Policy Consultant, Toronto; J. Mitchell, Anthropologist/Information Manager, Canada Department of Agriculture; R. A. Schulz, Faculty of Management, University of Calgary; W. H. C. Simmonds, Engineer/Sociologist/Futurist, National Research Council of Canada (retired); G. Sprakman, Organizational Design Analyst, Government of Alberta; J. A. Wojciechowski, Philosopher of Science, University of Ottawa.

tualist thought of the past two decades. He emphasizes the rationality of systems over that of individual optimizers, clearly paralleling the work of the French structural anthropologist Claude Levi-Strauss (and the structuralist movement in general). That is, in Heiner's model, it is the *system* that is rational, not the individual. Individuals cannot optimize; it is beyond their competence. This amounts, as Heiner noted, to dropping the basic rationality assumption from economics. The assumption has been necessary, up to now, because an uncertain subject implied unpredictable behavior. But, if it is uncertainty that produces predictable behavior, then the subrational subject is embraced within a rational (rule-governed) system. This implies a shift in the orientation of economics from the individual maximizer to the consideration of systems. It also reverses the implication of the previous paragraph. If it is the system that is rational, then Heiner is saving the Invisible Hand at the expense of economic man. The crucial link in this paradox is the role of *conscious* effort.

The two previous paragraphs suggest that Heiner may be writing a general theory of society rather than economics (or *more* than economics to be precise). That is, he may be looking at social behavior from a very high mountain top or a so-called God's eye view, and in an evolutionary time scale, rather than in the short-run horizon of an entrepreneur, bureaucrat, politician, or social reformer. If so, what is the importance of his work in the context of contemporary problems? Will it help take the heat off economists for the current state of the world?

Student enrollment in economics and job opportunities for graduates are flat while those for management students have increased dramatically over the past fifteen years. Are other disciplines dealing with reality more effectively than is economics? If economists are going to address broad questions of social theory, as Heiner is doing, other specialists must concentrate on principles and practices of effective and satisfying social action. What will Heiner's model do in terms of suggesting new questions that may help resolve old problems? One thing that an intelligent hierarchy needs is an understand-

ing of which specialists deal with what problems.

Our chief concern beyond the issue of this paper, or of economics generally, is that the *C-D* gap is growing beyond the capacity of any known optimization technique, and that more and more conscious effort is required to deal with the threat to survival that this implies. We believe that economists should be helping to reduce the problems of "info glut" and of decision-making uncertainty. Too often it is simply assumed that someone else will solve the problem. It would be very unfortunate if Heiner's work were to encourage dogmatic slumber and faith in an Invisible Hand at a time when concerted and conscious effort is required to design new institutions that subserve enlightened values and ethics. That conscious effort is necessary is implied, we believe, by Heiner's demonstration in his paper in this session that if an agent or system is to maintain its performance level in the face of an increasingly complex environment, it *must* find reliable ways to use increasingly complex information. This is an example of a problem area that should appeal to economists.

## II. Sources of Predictable Behavior

Behavior is a compound of three main factors: physiological, psychological, and rational. The physiological factors cover basic human needs and are everywhere similar. They are universal, hence predictable. Psychological factors are more complex and may be further subdivided into feelings and desires. Feelings appear to be similar in most persons, races, and cultures. They are near universal, hence predictable.

Desires, however, are more complex. Desires are not stable. They vary over time and are hard to predict. They grow; they can be stimulated. We blow them up; they become obsessions. They are the driving force in society. They also vary from one culture to another, and thus cannot be taken for granted in economic theory. The growth of knowledge and technology provide material for desires to feed upon.

Rational factors, the creations of the thinking brain, are the most change-inducing

and the least predictable. They are also growing, for knowledge is cumulative. The more knowledge we have with which to rationally serve desires, the less predictable is the outcome. The system becomes more and more open for the generation of knowledge is also the generation of ignorance. Each of us is today relatively far more ignorant than was a well-educated person at the dawn of the nineteenth century. And as more and more powerful knowledge becomes available to more and more people, it becomes more and more true that anything can happen. This link between uncertainty and abundance of information is more positive and direct than Heiner has drawn it.

In applying his theory to organizational behavior, Heiner used a biological analog. Biological systems are hierarchal. For a system to be effective or powerful, it must not only have the benefit of specialization of functions, but also many things must be "forgotten" by subunits. Whereas an amoeba must respond to all things connected to its welfare, a multicellular organism admits of specialization and some cells can "forget" about the responsibilities of some of the others. Yet, there must be linkage between them and a kind of intelligence or overview above them. This is the function of the central nervous system (CNS).

Heiner predicts that organizations will become more flexible as they become more complex, just as do other higher forms of life (man having the most sophisticated CNS). Just as an organism must evolve internal rules of behavior if its separate parts are to coexist in harmony and support their common life, so must the organisms that comprise an organization. Social insects, flocks of birds, and herds of mammals are examples, as are tribes among humans. Successful companies and industries also evolve by gradual establishment of heuristic rules of behavior. The organization defines itself by its own experience of what "works" vs. what does not work. This becomes a corporate culture, or knowledge construct. At least part of this might be called rational behavior that is non-conscious.

Ethnic or national cultures evolve in a similar heuristic way. Culture may be de-

scribed as a set of social rules that groups of people live by. These may be discovered by deliberately, methodically breaking them until the unwritten social rule is manifest. Most people are not conscious of the rules (culture) by which they are living. They only know when confronted with aberrant behavior that "we don't do it that way here." We are not conscious of our accent, our culture, or our world view until it is jarred. To the extent that cultures and world views help their bearers to survive, they may be called rational, as discussed above.

From a neurophysiological viewpoint, the process can be explained by "triune brain" theory. Culturally determined behavior (i.e., subconscious) is probably due to human interactions that involve primarily the limbic system of the brain rather than the cerebral cortex. The limbic system governs emotional responses that lead a person to discover for himself behavioral rules of the family, tribe, or other organization.

This subconscious, emotionally centered learning process has probably been a part of social behavior since before the emergence of man. In this century, students of scientific method have abstracted it to a system or principle called conjecture and refutation. The role of emotion in cognition explains why it has taken so long for mankind to become self-conscious of cognitive process: the limbic system attaches emotive value to ideas generated in the neocortex, and the limbic function of socializing overrides neocortical doubt. The consequence of this emotional-cognitive interaction is that group ideologies are hard to break.

This accounts for our frequent blindness to the fact that parts of our personal worldview or professional paradigm are inconsistent with the facts of observation. In the first place, there is the desire to be one with the herd, to stick to group norms. Beyond that, habitual or patterned ideas and behaviors may persist in spite of knowledge to the contrary, because facts and rational arguments may have insufficient emotional impact for our limbic system to "take cognizance" of them.

Another view of predictability comes from management science and is closely related

to economics itself. Predictability entails some stability of behavior patterns. Each of us has a personal stake in having many things remain as they were. There is an economy of decision making in habitual behavior. There is consequently a value to resisting change until the evidence becomes overwhelming. It saves us from the hard work of thinking.

### III. Implications of Unconscious Rationality

In our multidisciplinary interactions, some unease was exposed regarding what seemed a too-easy presumption of rationality by Heiner. Can it emerge automatically when thinking requires such effort? Bertrand Russell is reported to have said that many people would rather die than think. (In fact they do.) Death in preference to thought is a pretty strong aversion. Other trenchant thinkers have observed and marvelled at the phenomenon: Aldous Huxley, Arthur Koestler, Karl Popper, Erich Fromm, José Ortega y Gasset, Edmund Burke, to name a few.

We wonder how far the evolution of intelligent hierarchies can go without conscious thought and deliberate effort? Who is going to put together the rules for the next stage of social evolution? Do economists wish to leave it up to planners, organizational designers, political scientists, lawyers, and legislators? Or are they still promoting the political/economic model invented by eighteenth-century rationalists (liberalism) and adopted in the political constitutions of most Western nations? Economists seem easily to forget that the system of market capitalism is a political contrivance, a deliberate creation, that their own intellectual ancestors built it, and that they are its maintenance men or priestly class. The implicit attitude of most standard economic work is that the system is simply there, and the "scientific" aspect is to "discover" how it works. On the other hand, economists keep up the pressure to encourage everyone to believe in the market metaphor of society—that the pursuit of self-interest is rational for both individuals and for society at large.

What model of society is implied by Heiner's prediction that institutions have to

evolve that allow individuals or groups to know relatively less about each other and the whole? Does he envisage the development of a strong social central nervous system governed by an holistically rational brain at the top? Or is he offering an explanation of the unseen hand that turns atomistic rationality (self-interest) into the good of the whole? Is he suggesting that members of Western cultures have a sixth sense which enables them to understand instinctively without conscious effort, and to reject self-interest actions that would be damaging to the interest of the whole? Will every primitive man touched by the desire for Western goods instantaneously be converted into a similar marvel? Are we talking about economic man circumscribed by an ever-more complex web of regulations and controls, or about economic superman who knows without thinking and automatically selects only those self-serving actions that are also consistent with the welfare of all others? Is system rationality an automatic blessing, or a product of conscious effort?

To say that organizations that survive have adaptation capacity does not warrant a finding or rule that, as organizations become more complex, they also (necessarily and simultaneously) become more flexible. There have been plenty of organizational dinosaurs and there will be many more. An organization may last a long time without being very flexible or adaptable. The corporate culture may be fallible, yet untested by stress. The same is true of ethnic and national cultures. Fallibility shows up when major environmental change imposes severe stress. This has been happening all over the developing world as uncomprehending people demand Western goods but reject the Western culture that makes having them and using them possible.

That institutions must evolve which enable each agent in the society to know less and less about the behavior of other agents, and about the complex interdependencies generated by their interactions, is an implication of Heiner's theory, but the theory does not provide much insight into the mechanism of change in social institutions. We agree with the statement, but fear that it will not happen by assumption. More than ever, and

with increasing speed and intensity, cultural and institutional evolution must be conscious and deliberate. Man lives more and more in a world of his own making and can no longer rely on everything working out for the best.

#### IV. Limitations of the Ultimate Resource

We noted earlier on that the generation of knowledge is also the generation of ignorance. The capacity of our brains to process the information available to them is challenged by the very productivity of the brain itself. *Attention* may be the most limiting resource.

The difficulty of making intelligent decisions, whether personally or in an organization, has changed from ability to get information to one of processing a super abundance. Responsibility for processing and refining information into intelligence may be delegated but advisors become neurotic because they cannot cover the field. This leads to a corollary neurosis in decision makers: they can claim that a decision was rational (optimal) given the information available, but there is a good chance that inconsistent information could have been found, and that some persons may find it after the fact and confront the decision maker with it.

Knowledge and the power it conveys have had the effect of magnifying desires and expectations of people everywhere, yet the complexities and uncertainties manifest in infoglut are limiting our ability to satisfy those desires. The magnification of desires compared to capacity for fulfillment is increasingly dangerous in a world where the disgruntled can exert great destructive leverage against big systems using powerful but small-scale technology. The recent cases of poisoned pharmaceuticals and food products are examples.

Neuroses generated by this growing *C-D* gap have inspired a variety of coping strategies or behavioral rules that include collusion and conglomeration. Government regulation is another, counter, means. This leads to a reaction against complexity and collectivity. The catch is that most developing problems require more knowledge for their solution,

and the knowledge industry requires some kind of collective support, whether by corporate retained earnings or government collected taxes.

Thus, our desires for goods, thrills, power, and freedom are inconsistent with the complexity, discipline, and collectivity that seem necessary to achieve them. The ultimate desire is to have no constraints on the fulfillment of desires. That this may not be possible is hinted in the etymology of economics which suggests the orientation of a householder managing on a limited budget.

During most of the modern era there has been a tension between technological optimists and skeptics. Malthusians and conservationists/environmentalists have pointed to natural limits to human progress. Fred Hirsch called attention to social limits. Cognitive, cultural, and psychological limits are implications of territory that Heiner has opened up. We have serious doubts about the efficacy of what Julian Simon has termed the ultimate resource—unless the mind is turned toward accepting and coping with the limits to desire satisfaction instead of trying always to transcend them.

The ability of persons and societies to act “rationally” in both the economic and neurophysiological senses is decreasing due to the growth of knowledge. The pursuit of short-sighted self-interest (with knowledge power) contributes to danger and ungovernability, to psychosis, police state law and order, and to warfare. Dissatisfied, uncertain and neurotic people are a set up for demagogues and dictators. The rules that we need to adopt as a defense against the *C-D* gap are brotherly love, compassion, and cultural solidarity. (Many students of Public Choice Theory claim, in contrast, that these precise elements can be ignored.) A consciousness of collective values and purposes is required for the intelligent hierarchy. Through their continuing emphasis on the market metaphor as a social ideal, economists have been contributing to social breakdown by persuading people, intentionally or not, to ignore the implications of their personal actions for the common welfare.

Faith in an Invisible Hand is an expression of technological optimism. Economists

are its custodian, but they have never to our knowledge made a convincing case for how and why it will work in the long run. Heiner's work seems to be heading in the direction of showing that it will not.

## INTERNATIONAL FINANCE<sup>†</sup>

### The Changing Environment of Central Bank Policy

By ALEXANDRE LAMFALUSSY\*

It was more than a year ago that Charles Kindleberger extended to me his flattering invitation to address this joint meeting of the AEA/AFA. At that time we discussed various possible topics, but eventually decided to leave the title as vague as possible, on the grounds that this should allow me to take up the intellectual challenge of speaking on whatever financial crisis might have conveniently cropped up by the time of the meeting. Well, much in line with the fate besetting current economic forecasting, our timing was amiss: no crisis seems to be at hand.

I do not want to take the easy way out by frightening you with possible future crisis scenarios, only to end up by trying to persuade you that (despite the numerous wrongdoings of governments and even the occasionally silly behavior of market participants) the naturally enlightened and effective cooperation between central banks will either avert the crisis or at least contain it. As an alternative to this somewhat uninspiring approach, I propose to offer you a few reflections on some of the more fundamental problems that monetary policymakers are facing today, both domestically and internationally, and for the handling of which they would be delighted to receive from the academic community some operationally usable advice—the stress being on “operationally usable.”

I should like to focus my comments on two points. The first is that the financial

systems of the main Western industrial countries are in the midst of not one but, in some cases, as many as four interconnected evolutionary processes: disinflation; internationalization; innovation; and deregulation. The second point is that unless I am hopelessly behindhand in my readings, economic theory provides us with only limited guidance for managing our monetary affairs in such a complex process of structural adjustment and institutional change; nor can the observation of history give us much help towards understanding a situation which seems to be without precedent.

Let me begin with a few remarks on the management of the disinflation process. Under the impact of concerted anti-inflationary monetary policies initiated in 1979–80, inflation rates have over the last few years been declining more or less rapidly in all industrial countries. With the exception of a few countries they are, however, still at levels which would have been considered alarmingly high during the early 1960's. Moreover, what we know both from survey data and by inference from the level of interest rates suggests that inflationary expectations have been even slower to move downwards. The crux of the matter is that a slow process of disinflation of this kind carries with it, almost by definition, a good deal of uncertainty regarding future inflation rates—otherwise inflation could not be so sticky. This, in turn, implies that a considerable number of market participants are entering into contracts on terms that will inevitably prove costly for them; in other words, we are far from having seen the last of the casualties, either in the field of international lending or domestically, that are the normal corollary of disinflation. At the same time, the very slowness of the

<sup>†</sup> Presented at the AEA/AFA Joint Luncheon.

\*General Manager, Bank for International Settlements, Centralbahnplatz 2, Basel, Switzerland 4002.

process also implies a continued high cost in terms of unused resources and unemployment. For both these reasons, there is the risk of a political reaction against the process of disinflation itself. On the other hand, an anti-inflationary shock treatment might well have been even more painful, with heavy costs being implied in both the short and long run.

These developments raise at least two sets of questions for policymakers. First, is there any practical alternative to slow disinflation? Is "shock treatment" a genuine alternative? Note that history provides us with good examples of quickly successful disinflation only after phases of hyperinflation, not after the sort of long-lasting, creeping inflationary process which has permeated and distorted most of our Western industrial countries over the last fifteen years or more. In the absence of historical precedents, can theory provide any guidance? There have been a few interesting pieces of analysis of the question of shock treatment vs. gradualism, but the academic debate has remained remarkably scant.

Second, on the assumption that the current policy course is the only practicable one, what are its implications for the prudential side of central banking policies? Can manifestations of financial fragility be taken care of by the normal market mechanism, or does their containment require specific lender-of-last-resort intervention by central banks in order to prevent domino effects? Here, too, I would much welcome a wide-ranging theoretical debate on the mechanics of financial adjustment during a slow process of disinflation, as distinct from crisis manifestations at cyclical turning points.

While I could imagine convincing answers to these questions when viewing the process of disinflation within one closed economy, my imagination begins to falter when I look at this process within the framework of the growing internationalization of domestic banking systems. Whatever ratios you care to consider—the share of external claims or liabilities in the total balance sheet, the relative importance of balance-sheet items in foreign currency, the size of income flows derived from international operations—they

all point to a large and increasing international exposure of the domestic banking systems. The story of financial integration is also reflected in the cross-border transmission of interest rate developments. Interest rate parity holds almost instantaneously in the Euro-currency market; but, what is more important, there is growing statistical evidence of strong interconnections, even under floating exchange rates, between interest rate developments in the major domestic markets. Moreover, the fact that a number of countries, and within these countries private firms, are indebted in foreign currencies means that interest rate developments in these currencies can have a totally unexpected impact on the financial ratios of such debtors. In general, financial impulses emanating from the United States are transmitted remarkably quickly to other financial centers, despite fairly generalized floating. Interest rate "de-coupling" has been possible only within certain limits and by certain countries. Similarly, floating has not prevented strong international transmission links via the "real" side of the business cycle either.

In the best academic tradition, much recent research has gone into analyzing the implications of this state of affairs for exchange rate determination and for the international transmission effects of shifts in the policy mix of a large country, in particular of the United States. This research confirms the day-to-day experience of policymakers, namely that in a financially integrated world no country can isolate itself from the others, no matter what its exchange rate regime. To mention just one example, even determined domestic anti-inflationary policies can be thrown off balance by a real effective exchange rate depreciation induced by capital flows. This clearly raises major policy issues to which there are no unequivocal answers, but I certainly have no grounds for accusing academic researchers of any benign neglect of these problems.

I do, however, have the uneasy impression that insufficient academic work has been devoted to analyzing some other implications of international financial integration. One specific problem area concerns the question of whether the growing across-the-border in-

terdependence increases, or, on the contrary, diminishes the fragility of the Western countries' banking systems. More perfect competition would seem to point to greater resilience, that is, to the ability of the system to take care of itself without any lender-of-last-resort intervention. On the other hand, it does not seem evident to me that more active competition in some fields (i.e., internationally), coupled with continued market imperfections in others (i.e., domestically), add up globally to more perfect competition. I shall return to this question shortly, when reflecting on the subject of deregulation. Another much broader area concerns the normative evaluation of the effects of greater financial integration (i.e., of speedier and much larger financial flows) on a world economy in which international direct investment flows remain limited and which at the same time is exposed to increasing trade barriers or to new types of trade distortions (for example, countertrade). This is Bretton Woods turned upside down—a kind of topsy-turviness which, in my physiocratic simplicity, I view with some suspicion.

The third evolutionary process has to do with the accelerating speed of financial innovations, particularly in North America and the United Kingdom, but also in quite a few other countries, though there, perhaps, attended by less publicity. This process is fueled by market participants' desire to hedge against the uncertainty generated by interest and exchange rate volatility (and is thus partly a reflection of inflationary developments), to circumvent regulations or to avoid taxes, to take up opportunities offered by deregulation or new technology, or simply to respond to market pressure. The result is a flow of new instruments and new techniques, and the blurring of dividing lines between institutions as well as between markets.

Central banks operating in such a fluid environment encounter a variety of problems. There is the problem of identifying suitable targets among the monetary aggregates, broad and narrow, and of recognizing circumstances when it seems appropriate to deviate from these targets. At a time when almost all bank liabilities are beginning to carry interest, I fear that the concept of

transactions balances itself may be becoming elusive. Then, second, there are problems related to the narrowly defined monetary control techniques, that is, to the operational methods by which central banks try to hit their targets. Third, central banks would like to know whether and, if so, how the transmission mechanism from these targets to nominal income is affected, for example, by the proliferation of new instruments, the spreading use of floating interest rates or of financial futures.

Fourth, there are the prudential implications of innovation. What should be done, for instance, on a purely technical level, with a number of balance-sheet items listed as contingent liabilities, or with the host of intermediary balance-sheet items classed somewhere between equity and "traditional" liabilities? How should minimum capital ratios be established? Should such ratios be established at all? Are they not going to produce "evasive" innovations? What are the macroeconomic implications of assigning greater control responsibilities to the supervisory authorities? More fundamentally, we should try to assess the systemic effects of the redistribution of risk realized by means of some of these new techniques and instruments. You may argue that when risk-averse market participants shift risks associated with unexpected interest and exchange rate developments onto willing risk takers, everybody is going to be better off. This may well be the case, but increased collective happiness does not necessarily mean greater systemic stability. Or does it?

The difficulties in analyzing these problems and, therefore, in establishing policy-oriented value judgements are aggravated by two aspects of the current trend in innovations. One is that many of them also have an international dimension. Take the example of swapping a fixed interest claim in one currency on a foreign debtor against a variable interest claim in a different currency on a domestic borrower. Note, at the same time, that the legal obligations attached to a swap are so difficult to define, even within one legal system, let alone when several systems are involved, that the word itself cannot be translated unequivocally into the legally very

precise French language. The point is that I am far from sure that all participants in these swaps fully appreciate the commitments they take on. Second, and more importantly, we are confronted here with a continuous *process*, rather than occasional discrete steps followed by a lengthy pause. There is no time for market participants to adjust themselves fully; the process is truly a dynamic one. Take, for instance, the gradual merging of the Euro-bond market with international bank lending, which is progressively eroding the usefulness of traditionally defined international banking statistics and removing the little transparency which we have managed to create in this particular field. What could be the consequences of this vanishing transparency for the decision-making process of market participants or for policymakers?

Let me now say a few words about deregulation—a topic of great interest in this country as well as in others. This, too, is an ongoing process, rather than a quantum jump from a fully regulated to an entirely free financial system. And if we consider the worldwide financial system, it becomes evident that we are condemned to live with a hybrid system even if the legislature of any single country were to accept such a quantum jump—a remote possibility anyway.

What guidance can theory offer to central banks managing their monetary policy or discharging their prudential duties in this environment? Note that the question is not only whether an entirely free financial system is more efficient (whatever that may mean), or more stable, or more easily “controlled” (in the sense of monetary control) than a regulated one. That is an interesting question but one of little immediate practical relevance. What I should like to know is, first, how the *process* of deregulation, with its inevitable lopsidedness and uncertainties as to the next steps, is working out in practice; and, second, how it could be improved. A deregulated world might be better than a fully regulated one, but a lot can happen on our way from the latter to the former.

I apologize for having presented such an indigestible menu of what might look like institutional trivialities, but I think that quite a lot is at stake. I have in mind in particular

the need to preserve the useability of monetary policy as the main macroeconomic policy instrument. The practical or fundamental limitations of fiscal policy have become obvious: with government expenditure absorbing a very high proportion of resources, few Western European countries have any margins of maneuver for stimulatory fiscal policies, while, for reasons that you know only too well, the United States seems to have got stuck in the opposite direction. In such circumstances, impaired useability of monetary policy would surely have to be counted as a social cost to be set against the benefits of innovation and of deregulation in any global cost-benefit analysis.

Those of you who are familiar with ancient writings will by now have discovered my nostalgia for one of Schumpeter's main themes, namely that economic analysis should concern itself with the process of change, with its succession of cumulative or compensating imbalances, rather than with movements around some identifiable state of equilibrium. When I read his writings, more years ago than I care to remember, I hardly understood what he had in mind and dismissed it anyhow because I could not convert it into equations. As a professional participant in the current process of change affecting financial markets, and having to advise central banks on how to operate in such an environment, I am beginning to have an inkling of what he was driving at—although I am less able than ever to put these thoughts into a rigorous theoretical framework. If some of you could, I am sure that practitioners of monetary policy would appreciate it.

In the meantime—“*en attendant*” as we would say more appropriately in French—practitioners will have to continue to practice. They cannot simply resign and take up gardening, much though some of you might wish them to. For my part, in my advisory capacity, I try to prevent them from succumbing to two opposite temptations.

One temptation is to return to complete “*ad hoc*-ry,” that is, to what the French would call “*naviguer à vue*.” This would be a grave mistake. Full discretion cannot counteract uncertainty; in all likelihood it increases it. Rules, be they monetary aggre-

gates or an exchange rate target, are needed to provide some anchor for the wildly fluctuating expectations of market participants; to make monetary policymakers accountable for their action, including their decisions to deviate from predetermined targets; and to give them leverage in their dealings with governments and parliaments.

The other temptation is to retreat into a world of rigid rules. I hope that I have made it abundantly clear why in the present world

environment I do not believe in a monetary policy based on mechanical rules. It is difficult to define such rules; it is sometimes impossible to apply them; and it would often be irresponsible to stick to them.

The road to follow is somewhere in between: rules applied with a pragmatic sense of discretion. Admittedly, this is more easily said than done, but then monetary policy, like all other policies, remains an art not a science.

AMERICAN ECONOMIC ASSOCIATION

---

PROCEEDINGS  
OF THE  
NINETY-SEVENTH  
ANNUAL  
MEETING

DALLAS, TEXAS  
DECEMBER 28–30, 1984

Minutes of the Annual Meeting  
Dallas, Texas  
December 29, 1984

The Ninety-Seventh Annual Meeting of the American Economic Association was called to order by President Charles Schultze at 5:45 P.M., December 29, 1984 in the Dallas Convention Center. The minutes of the meeting of December 29, 1983 were approved as published in the *American Economic Review, Papers and Proceedings*, May 1984, p. 425.

The Secretary (C. Elton Hinshaw), Treasurer (Rendigs Fels), Managing Editor of the *Journal of Economic Literature* (Moses Abramovitz), Associate Editor of the *American Economic Review* (John Riley), and the Director of *Job Openings for Economists* (Hinshaw) discussed their written reports which were distributed at the meeting. (See their reports published elsewhere in this issue.)

Schultze announced that Orley Ashenfelter had agreed to become managing editor of the

*American Economic Review*, replacing Robert Clower. The transfer of the editorial office will take place in early 1985. He also announced the Executive Committee's decision to initiate steps necessary for the publication of a new journal designed to bring to the general economist the results of frontier research, articles applying theory to policy issues, and information useful to teachers; the new President has been authorized to begin the search for an editor. Schultze then introduced Charles Kindleberger, the 1985 President of the Association, to the audience.

There being no further business, the meeting was adjourned.

Respectfully submitted,  
C. ELTON HINSHAW, *Secretary*

## Minutes of the Executive Committee Meetings

**Minutes of the Meeting of the Executive Committee in Washington, D.C., March 23, 1984.**

The first meeting of the 1984 Executive Committee was called to order at 9:10 A.M. on March 23, 1984 in the Conservatory Room of the Washington Hilton Hotel, Washington, D.C. Members present were Charles L. Schultze (presiding), Gardner Ackley, Rendigs Fels, Victor R. Fuchs, Zvi Griliches, Robert L. Heilbroner, C. Elton Hinshaw, Charles P. Kindleberger, W. Arthur Lewis, Janet L. Norwood, and Joseph E. Stiglitz. Present for parts of the meeting were members of the Nominating Committee: William J. Baumol (chair), Clair Brown, Robert M. Coen, John G. Gurley, Stanley Lebergott, Glenn C. Loury, and Richard H. Thaler. Lawrence R. Klein, chair of the Search Committee for the *American Economic Review* Editor, and Katherine K. Wallman, Executive Director of the Council of Professional Associations on Federal Statistics, were present to make reports.

*Minutes.* The minutes of the meeting of December 27, 1983 were approved as written and circulated prior to the meeting.

*Report of the Secretary* (Hinshaw). The Secretary reported that the 1984 annual meetings will be held in Dallas, Texas on December 28–30, and the next meeting of the Executive Committee will be December 27. The sites for subsequent meetings are New York (1985) and New Orleans (1986). Boston and Chicago are under consideration as sites for the 1987 meetings.

Registrations for the 1983 ASSA meetings in San Francisco totaled 5,735. Forty associations organized 390 scholarly sessions. In 1974 when the meetings were last held in San Francisco, 5,431 people registered and 21 associations organized 196 sessions. The Secretary discussed some of the difficulties the growth in sessions caused for planning, organizing, and coordinating the meetings. The Executive Committee expressed concern that the quantity of papers and sessions was growing faster than their quality. It recommended that regional associations not be allowed to join the ASSA, and that the AEA

President-elect exercise great care in agreeing to joint sessions with other associations. It was understood that it would be desirable to limit or reduce the total number of joint sessions, possibly imposing a limit of 2 joint sessions per association.

The Secretary announced that a directory of members would be published in 1985 as a special issue of the *American Economic Review*. Because of the peculiarity of postal regulations, it is cheaper to publish articles along with directory information than to publish only directory information. The President was instructed to appoint a committee to select articles for the publication.

*Program for 1984* (Kindleberger). He reported that 39 sessions were complete, 29 virtually complete, and enough loose ends that would probably produce about 10 more. Schultze noted that Milton Friedman had written to him lamenting the past decisions of Presidents-elect not to publish comments in the *Papers and Proceedings*. Kindleberger indicated that the next issue would indicate who the discussant of each paper was and that the comments would be available but not published. It was agreed to continue to leave the decision to publish or not to publish comments in the hands of the President-elect. In response to a question about paying the transportation cost of distinguished speakers and various honorees to the annual meetings, it was decided not to pay such expenses.

*Surplus Committee* (Schultze). There appears to be a great interest in publishing a third journal of a nontechnical nature. He reminded the Executive Committee that it had authorized him to spend up to \$25,000 for a feasibility study. He is still searching for someone to do the study. He thought that it was not now possible to have a "sample, dummy copy" of the proposed journal by December, but that substantial progress would have been made by that time on determining whether to proceed or not.

*Council of Professional Associations on Federal Statistics* (Wallman). Wallman, the Executive Director of COPAFS, reviewed the

highlights of her annual report, a copy of which is available from COPAFS, Suite 440, 806 15th Street, N.W., Washington, D.C. 20005. It was decided to become more involved in and aware of COPAFS activities.

*Nominating Committee* (Baumol). The Electoral College, consisting of the Nominating and Executive Committees meeting together, chose Alice M. Rivlin as the nominee for President-elect and Evsey S. Domar and Albert O. Hirschmann as Distinguished Fellows. Baumol reported the following nominees for other offices: for Vice-President (two to be chosen), Elizabeth E. Bailey, Gerard Debreu, Thomas C. Schelling, and Joseph E. Stiglitz; for members of the Executive Committee (two to be chosen), Marcus Alexis, Alan S. Blinder, Daniel McFadden, and Sherwin Rosen.

*Search Committee for AER Editor* (Klein). Klein reported that the Committee had reduced the number of possible candidates to two or three. He expected to have a recommendation prior to the December 1984 meetings of the Executive Committee.

*Other Business*. A. W. Coats, Crawford D. Goodwin, and Laurence S. Moss had written requesting the Association to provide an initial grant to support a systematic investigation of the available archival sources within the United States, especially the unpublished papers and correspondence of leading American economists. It was decided (a) to give general approval of the undertaking, (b) to support the application for a grant from an appropriate body after the completion of an acceptable pilot study, (c) but not to provide funds for the project at this stage.

William D. Gunther, Executive Secretary – Treasurer of Omicron Delta Epsilon, had written asking the Association to share in financing and sponsoring a booklet on careers in economics. Interest was expressed in helping with such a project, but several objections were raised concerning the submitted draft. It was indicated that the Association would participate if a more appropriate document was developed.

Samuel H. Williamson and James Dunlevy, both of Miami University, had written recommending that the Association appoint a committee to establish a standard procedure to be used in generating departmental rank-

ings. It was agreed not to become involved in attempts to determine departmental rankings.

*Report of the Editor of the Journal of Economic Literature* (Moses Abramovitz). Abramovitz wrote that the transition in the Pittsburgh office from Naomi Perlman to Drucilla Ekwurzel was going smoothly. The 1979 edition of the *Index of Economic Articles* will go to press by June and will be published in the fall. The 1980 edition should go to the printer by the end of the year. Abramovitz and Asatoshi Maeshiro, who now has full responsibility for the classification of articles for the *JEL*, are beginning a review of the list of journals indexed by the *JEL*. No such review has been made since the *JEL* began.

*Report of the Treasurer* (Fels). Using the investment income formula adopted in the late 1960's, the Association's audited financial statements show a surplus for 1983 of \$245 thousand. The surplus would have been \$437,440 if changes in the market value of stocks, after adjustment for inflation, had been recognized only but entirely in 1983. In the absence of decisions to undertake new projects or cut dues, the ratio of net worth to expenses is expected to continue to rise. The current ratio is 1.48.

The current dues structure discriminates (unintentionally) against non-academic members. Academics who are Associate or Assistant Professors may pay lower dues than non-academics even though their incomes are more or less the same since dues are based on either of two criteria, rank or income. The Budget and Salary Committee recommended the abolition of the rank criterion. It was VOTED that the Treasurer should draft an amendment to the bylaws abolishing the rank criterion and adjusting the income categories in such a way as to maintain existing revenues. The draft would be circulated to the Executive Committee for its approval and then submitted to a vote of the membership.

There being no further business the meeting adjourned at 4:30 P.M.

*Minutes of the Meeting of the Executive Committee in Dallas, Texas, December 27, 1984.*

*Call to Order*. The second meeting of the 1984 Executive Committee was called to

order at 10:10 A.M. on December 27, 1984 in the Garden Room of the Fairmont Hotel, Dallas, Texas. Members present were Charles L. Schultze (presiding), Moses Abramovitz, Gardner Ackley, Rendigs Fels, Victor R. Fuchs, Zvi Griliches, Robert L. Heilbroner, C. Elton Hinshaw, Charles P. Kindleberger, W. Arthur Lewis, Janet L. Norwood, A. Michael Spence, and Joseph E. Stiglitz. Also present were recently elected members of the 1985 Executive Committee (Elizabeth E. Bailey, Daniel McFadden, and Alice Rivlin) and Counsel Leo Raskind. John Riley, Associate Editor of the *American Economic Review*, sat in for Robert Clower. Present as guests for parts of the meeting were Barbara Bergmann, Donald J. Brown, Lee Hansen, David Richardson, and Bernard Saffran.

In his opening remarks, President Schultze welcomed the new members and thanked those leaving the Committee (Ackley, Griliches, Ann F. Friedlaender, and Heilbroner). He noted that Stiglitz had been reelected to the Committee as a Vice-President. He announced that Orley Ashenfelter had accepted the editorship of the *American Economic Review*; the transfer of the office from Clower would probably take place in March 1985.

*Minutes.* The minutes of the meeting of March 23, 1984 were approved as written and circulated prior to the December meeting.

*Report of the Secretary* (Hinshaw). Hinshaw reported that next year, the AEA's Centennial, the annual meeting would be held in New York during December 27-30; New Orleans would be the site of the 1986 meeting. It was VOTED to accept his recommendation of Chicago as the site for 1987. He announced that a new directory of members is planned as a special December 1985 issue of the *AER*. Since 1985 is the 100th birthday of the Association, a Committee (Moses Abramovitz, Charles Kindleberger, and George Stigler) had commissioned five articles appropriate for the occasion and the directory: "Early American Leaders—The Neoclassical Tradition," James Tobin; "Early American Leaders—The Institutionalist and Critical Tradition," Martin Bronfenbrenner; "The Beginnings of Empirical Economics in America," Carl Christ; "Changes in Methods of Analysis and Research," William

Baumol; and "The Expanding Domain of Economics," Jack Hirshleifer. He also announced that, based on a polling of the Executive Committee during the summer, he had entered into a contract to produce an AEA Centennial T-shirt as part of the 100th birthday celebration. (Samples were available.) It was VOTED to appoint a committee to investigate instituting a journal donation program similar to that of the American Psychological Association.

*Report of the Managing Editor of the American Economic Review* (Riley). Riley, Associate Editor of the *AER*, briefly reviewed Clower's written report (see elsewhere in this issue). He stated that for the first time in several years the number of submissions had not increased significantly; there has been a slight increase in the editorial decision lag over 1983; and about one-third of all submissions are returned without sending them to outside referees.

*Report of the Managing Editor of the Journal of Economic Literature* (Abramovitz). Abramovitz summarized his written report (see elsewhere in this issue). He noted the smoothness of the transition of operations in the Pittsburgh office and lauded the work of Drucilla Ekwurzel, who replaced Naomi Perlman as Associate Editor, and Asatoshi Maeshiro, Professor at the University of Pittsburgh, who serves as an Editorial Consultant with general responsibility for the classification of articles. Among other things, the new team has expanded bibliographic services of the *Journal*, published the 1979 volume of the *Index of Economic Articles* in November, and added abstracts of articles to the material available by computer through DIALOG.

It was recommended that more publicity be given to the availability of the *Indexes* and that the editor consider publishing an article on the use of on-line bibliographic services such as DIALOG.

*Report of the Director of Job Openings for Economists* (Hinshaw). See his written report elsewhere in this issue.

*Report of the Treasurer* (Fels). Fels reported (see his written report elsewhere in this issue) that the projected 1985 budget as circulated needed revising. The *AER* budget contained therein was submitted by Clower

and did not include sufficient provision for the cost of transferring the journal to Ashenfelter, the new editor, nor the cost of an expanded editorial office. Neither did it include the Budget Committee's decision to change the method of calculating investment income. The result of these two revisions changed the originally projected surplus of \$91,000 for 1985 to a small deficit. It was VOTED to approve the budget subject to revision, but to delay the change in the method of calculating investment income until the March meeting. The current method of calculating investment income recognizes equity income to include dividends and capital gains (realized or not) adjusted for inflation and spreads the income over three years; income from debt securities is recognized in the year received. The new method proposed by the Budget Committee would calculate investment income as 4 percent of the market value of the portfolio. The Treasurer was asked to compare the results of applying the two methods over the past fifteen years for the March meeting. He was also asked to request Stein, Roe and Farnham to report on their performance relative to that of the stock market indexes.

*Surplus Committee* (Schultze). Schultze reminded the Executive Committee that he had been authorized to hire a consultant to investigate the feasibility and costs of publishing a third journal. Bernard Saffran had conducted the study and reported his findings, copies of which had been circulated. The Surplus Committee had concluded, based on the Saffran report and its own deliberations, that a new journal directed primarily to publishing (1) frontier research in nontechnical language, (2) applications of theory to policy issues, (3) symposia, and (4) bibliographic material primarily useful to teachers was desirable and feasible. The two most attractive options were an entirely new journal and the division of the *Journal of Economic Literature* into two separate journals—one containing the article and book review sections of the current *JEL* plus the new material and the other containing the bibliographic sections. The Surplus Committee recommended an entirely new journal. Starting such a journal was considered a high risk but worthwhile venture. It was estimated that an

investment outlay of up to \$500,000 might be necessary to launch successfully the journal; this includes substantial outlays on editorial services which are not ordinarily provided by professional journals, sending several issues of the journal free to all members to help establish it in the market place, and up to a year of expenses before the production of the first issue. If successful, it was expected that the new journal could add up to \$200,000 net cost each year to the Association's expenditures. It was anticipated that members would be allowed to pick any two of the three journals (*AER*, *JEL*, and new journal) for their dues and could subscribe to the third for an additional sum. If the experiment was considered a failure, the new journal would be dropped.

Discussion of the recommendation covered the waterfront. One member expressed a feeling of uneasiness about the demand for the proposed journal; another questioned the adequacy of supply of appropriate articles. At least one member preferred to split the *JEL* into two journals; another suggested the possibility of assuming the editorial responsibility of an existing journal, such as the *Journal of Economic Education*, that attempts to address the needs of teachers. Several combinations of format, contents, and size were suggested. No one voiced opposition to the general idea of a third journal; some were enthusiastic supporters.

It was VOTED to publish a new, third journal and authorize the incoming President to seek an editor (or editors) enthusiastic about the concept of a journal directed to the perceived needs of the general economist. It was understood that an initial investment of \$500,000 might be necessary; annual net cost to the Association could be as much as \$200,000; it might take up to a year after an editor is found to produce the first issue; the first several (2 or 3) issues would be sent free to all members; a means of "marketing" the journal would be studied; and the new editor would report to the Executive Committee just as do the current ones.

*Committee on Economic Education* (Hansen). Hansen, who chairs the Committee, reported that there is a growing interest in the teaching of economics at the high school level; thirty states now require precollege

instruction in economics. He sought advice on whether formally to support minimal standards of training, such as at least one college-level course, for teachers. Views expressed on the value of supporting such a standard varied widely—from enthusiastic support to the belief that even minimal standards such as the one given as an example might do more harm than good. No specific advice was given.

*Committee on the Status of Women in the Economics Profession* (Bergmann). In addition to circulating a written report (see elsewhere in this issue), Bergmann stated that the major mission of the Committee was to promote women's participation in all the activities that economists are represented in and to promote getting more women represented in the economics profession. The Committee seeks ways to make the profession more hospitable to women. It was VOTED to appropriate \$15,000 for the activities of the Committee for 1985 and to allow the carryover of some \$13,000 from previous appropriations. It was understood that no "large" expenditure from the carryover would be made without prior approval of the Executive Committee.

*Committee on the Status of Minorities in the Economics Profession* (Brown). Brown reported that the University of Wisconsin hosted its second summer program for minorities in 1984. The Committee has begun the search for a host university for the three years after 1985. Wisconsin has offered to have the program for a fourth year (1986) if necessary. David Richardson briefly reviewed the 1984 program. There were 140 applicants, almost triple the number for the previous year; the 32 applicants accepted were better and more motivated than past classes; 20 of them had the potential to do quality graduate work; 13 or so had the motivation to do so. The 1984 program had been the most successful one to date.

Brown reviewed the status of the Rockefeller grant. In 1980, Marcus Alexis (previous

chair of the Committee) had received a \$350,000 grant to support the summer program, historically black colleges, and graduate fellowships for minorities at a five-school consortium. In 1983, the Federal Reserve System had agreed to support minority graduate students during their third and fourth years given that the Rockefeller grant supported them for the first two years. In part because the Sloan Foundation renewed its grant to support the summer program and because of the initial constraints placed on the granting of fellowships, very little of the Rockefeller monies had been spent by the scheduled expiration date of the grant. Rockefeller was willing to renew the grant provided the five-school consortium was disbanded, any school willing to forego tuition would be eligible for fellowships, and the Federal Reserve System would agree to support students for the third and fourth years. In summary, Rockefeller agreed to support, beginning January 1985, for three years a national fellowship program for minorities. It was VOTED to give approval to Brown to accept the grant on behalf of the AEA provided a satisfactory plan (in detail) for fellowship selection was presented to the Executive Committee at its March 1985 meeting.

*1985 Program* (Rivlin). Rivlin, President-elect and Program Chair for the 1985 meetings, stated that she was planning a special program to celebrate the AEA's Centennial. It would emphasize policy and the practicality of economics. She expected it to have more of a prospective view ("Where do we go from here?") than a retrospective one ("Where have we been?").

There being no further business, the meeting was adjourned.

Respectfully submitted,  
C. ELTON HINSHAW, *Secretary*

## Report of the Secretary for 1984

*Annual Meetings.* In 1985, the Association's centennial, the annual meeting will be held in New York on December 28–30. A special program is planned. The schedule for subsequent meetings is New Orleans in 1986, and Chicago in 1987. Each of these meetings is scheduled for December 28–30, and each will have a Placement Service, which will open for business one day earlier (December 27) than the meetings.

*Elections.* In accordance with the bylaws on election procedures, I hereby certify the results of the recent balloting and report the actions of the Nominating Committee and the Electoral College.

The Nominating Committee, consisting of William Baumol, Chair, Clair Brown, Robert M. Coen, John G. Gurley, Stanley Lebergott, Glenn C. Loury, and Richard Thaler submitted the nominations for Vice-Presidents and members of the Executive Committee. The Electoral College, consisting of the Nominating Committee and Executive Committee meeting together, selected the nominee for President-elect. No petitions were received nominating additional candidates.

*President-Elect*  
Alice Rivlin

<i>Vice President</i>	<i>Executive Committee</i>
Elizabeth E. Bailey	Marcus Alexis
Gerard Debreu	Alan S. Blinder
Thomas C. Schelling	Daniel McFadden
Joseph E. Stiglitz	Sherwin Rosen

The Secretary prepared biographical sketches of the candidates and distributed ballots last summer. On the basis of the canvas of ballots, I certify that the following persons have been duly elected to the respective offices:

*President-elect* (for a term of one year)  
Alice Rivlin

*Vice-Presidents* (for a term of one year)  
Elizabeth E. Bailey  
Joseph E. Stiglitz

*Executive Committee* (for a term of three years)

Alan S. Blinder  
Daniel McFadden

In addition, I have the following information:

Number of legal ballots	5,804
Number of invalid envelopes	167
Number of envelopes received after October 1	24
Number of envelopes returned	5,995

In accordance with the action taken by the Executive Committee at its March 23, 1984 meeting, an amendment to Article I, Section 2, of the bylaws was submitted to the members in a mail ballot in conjunction with the balloting for officers. I certify that the amendment was approved by a vote of 3,460 "for," 601 "against." The bylaws as amended now read:

### Article I, Section 2

There shall be six classes of members other than honorary: regular members with annual incomes of \$30,000 or less paying the base fee defined below; regular members with annual incomes above \$30,000 but no more than \$40,000 paying one and one-fifth times the base fee; regular members with annual incomes above \$40,000 paying one and two-fifths times the base fee; family members (persons living at the same address as a regular member, additional memberships without subscription to the publications of the Association) paying one-fifth of the base fee; junior members (available to registered students for three years only) paying one-half the base fee; and life members comprising those who qualified for life membership by making a single payment of the designated amount prior to January 1, 1976, and exempt from annual fees.

Effective January 1, 1976, the base fee is \$25.00 per year. The Executive Committee may increase the base fee in

proportion to the increase occurring after January 1, 1976 in relevant price and wage indexes. It may increase the income brackets for regular members but may not decrease them below the figures specified in this bylaw.

*National Registry.* The National Registry for Economists continues to be operated on a year-round basis by the Illinois State Employment Service. Economists looking for jobs and employers are urged to register. This is a placement service that maintains the anonymity of employers. The Association is indebted to the Registry for assistance and supervision at the employment service provided at the annual meetings. Employers are reminded of the Association's bimonthly publication, *Job Openings for Economists*, and their professional obligation to list their openings.

*Membership.* The total number of members and subscribers is shown in Table 1. The total has fluctuated between 25,000 and 26,500 since 1975, when it reached an all time high of 26,787. Since then the increase in memberships has offset the decline in subscribers.

*Permission to Reprint and Translate.* Official permission to quote from, reprint, or translate and reprint articles from the *American Economic Review* and the *Journal of Economic Literature* totaled 265 in 1984, compared to 176 in 1983. Upon receipt of a request for permission to reprint an article, the publisher or editor making the request is instructed to obtain the author's permission in writing and send a copy to the Secretary as a condition for official permission. The Association suggests that authors charge a fee of \$150, but they may charge some other amount, enter into a royalty arrangement, waive the fee, or refuse permission altogether.

*1985 Directory.* A new directory of members is planned as a special December 1985 issue of the *American Economic Review*. Since 1985 is the 100th birthday of the Association, articles appropriate for the occasion have been commissioned for the issue. Members should expect to receive biographic questionnaires in early spring.

TABLE 1—MEMBERS AND SUBSCRIBERS  
(End of Year)

	1982	1983	1984
Class of Membership			
Annual	16,771	16,728	16,612
Junior	1,895	1,998	1,932
Life	384	383	370
Honorary	32	31	29

Subscribers	5,171	5,986	5,846
Total Members and Subscribers	25,257	26,148	25,732

*AEA Staff.* The Secretary is fortunate to have an unusually loyal and efficient staff. Mary Winer (Administrative Director), Kimberly Adair, Norma Ayres, Ersye Burns, Violet Sikes, Dale Wagner, and Jacquelyn Woods handle the day-to-day operations of the Association. Barbara Weaver and Marlene Hall plan and organize the details of the annual meeting. I wish to thank them for their dedicated work and good humor.

*Committees and Representatives.* Listed below are those who served the Association during 1984 as members of committees or representatives. The year in parentheses indicates the final year of the term to which they have been appointed. On behalf of the Association, I wish to thank them all for their services.

## Report of the Treasurer for the Year Ending December 31, 1984

The finances of the American Economic Association continue to be robust, though not as robust as projected a year ago. The budget for 1984, shown in the fourth column of Table 1, showed a projected surplus of \$288 thousand resulting from an operating deficit of \$72 thousand and an investment gain of \$360 thousand. It now appears that investment gains for 1984 will be considerably smaller than projected. Final audited financial reports for 1984 will be published in the June issue of this *Review*.

The fifth column of Table 1 shows the proposed budget for 1985 considered by the Executive Committee at its meeting on December 27, 1984. It shows an operating loss of \$151 thousand, an investment gain of \$242 thousand, and a surplus of \$91 thousand. A revised budget will be submitted to the Executive Committee for consideration at its meeting on March 22, 1985. The new budget will include additional expenditures for the *American Economic Review* resulting from appointment of co-editors. It will also show considerably smaller investment gains. The combined effect will be to project a deficit instead of a surplus.

The net worth of the Association, estimated at \$2.6 million on September 30, 1984, is well above what is needed for precautionary purposes. Ten years ago the Association survived a time when the net worth was negative, and for years it was below half of annual expenses. Inasmuch as the Association had a deficit in 1970 about half of its expenditures for that year, I have generally felt that a ratio of net worth to the coming year's spending of one-half was the prudent minimum. With expenditures for 1985 projected at less than \$2 million, a net worth of \$1 million would be adequate. This does not mean that the Association has excess funds of \$1.6 million. If it spends such a sum on start-up costs for the proposed new journal, investment income would fall below the operating loss, resulting in substantial deficits, liquidation of investments, and reduction in the net worth. But the funds available for the new project exceed a million dollars.

In 1983 a Surplus Committee was appointed to consider whether the Association should undertake a new journal. The Executive Committee on December 27 decided to do so and to launch a search for an editor. No provision has been made for such spending on the journal in the 1985 budget.

Recently, the Executive Committee has pursued a policy of not increasing dues rates in nominal terms, with the result that, after adjustment for inflation, real dues have fallen. But it recommended, and the membership approved, a change in the dues structure effective January 1, 1985, designed to correct an inequity without changing the revenues derived from this source. Formerly, there were two criteria for determining the applicable dues rate of a member, rank and income. The two criteria had become badly out of line with each other so that some non-academic members had to pay substantially more than academic members with the same income. To correct this inequity, the criterion of rank has been abolished and the salary brackets adjusted to current realities. Since the result otherwise would have been reduced revenues, the base rate for dues was simultaneously increased.

Even if the Executive Committee had not decided on a new journal, continuing existing policies would result in operating losses growing faster than investment gains. The recent surpluses are giving way to deficits. Soon, members' dues and/or library subscriptions rates will have to be increased. Subscription rates have remained the same since the beginning of 1981. Even at that time, they were not high compared to other journals. Inasmuch as demand is highly inelastic, the Association is in a position to raise more revenue whenever it wishes to do so.

The investment gains shown in Table 1 for 1983 and 1984 are calculated on the basis of the investment income formula adopted by the Association in the 1960's. The formula was based on the belief that (1) the Association could legitimately spend real capital gains, (2) the stock market is so volatile that

<sup>a</sup> Revenues for dues and subscriptions were not projected separately.

real capital gains from equities should be "recognized" in the income statement over a period of three years, evening out erratic shifts in stock prices, and (3) the surplus or deficit on the income statement when investment gains are so calculated provides a useful guide for decision making.

Although the principles underlying the investment income formula are sound, we are considering phasing it out. It is too complex; a simpler guide to decision making is needed. Moreover, the experience of the last decade and a half has shown that what matters for decision making is the adequacy of net worth

relative to annual expenditures. If the net worth is high, as is presently the case, deficits are legitimate; if the net worth is negative, as it was ten years ago, a balanced budget is not enough. The last line of Table 1 accordingly shows the ratio of net worth to annual expenditures. (In each case the ratio is based on the net worth at the beginning of the year except that, for 1985, the net worth on September 30, 1984, is used.) It should be kept in mind that the ratio is subject to the vagaries of the stock market.

The investment gains for 1983 and 1984 in Table 1 result from using the investment

income formula. Of the \$199 thousand for the first nine months of 1984, \$158 thousand represents one-third of the real capital gains from equities in 1982 and 1983, recognition of which was postponed to 1984. The projected investment gain for 1985 was calculated by applying the historic real rate

of return on equities (6.5) to the portfolio of equities and adjusting for expected inflation of 4.5 percent the estimated yields from other assets.

RENDIGS FELS, *Treasurer*

## Report of the Finance Committee

The Finance Committee of the American Economic Association met at the Chicago Club, Chicago, Illinois, at noon on December 11, 1984. Present were Committee members Rendigs Fels (Chairman), Robert Eisner, and Robert Genetski. Also present were Harvey Hirschhorn, Robert McNeill, and James Weiss of Stein Roe & Farnham, the investment counsel of the Association. Sidney Davidson was absent.

Mr. McNeill presented a written report which included the minutes of selected past meetings charts and tables relating to market performance, data on the portfolio of the Association, and an economic forecast. For the period from December 1977 to November 1984, the total return on the Association's portfolio was +104.1 percent. On the fixed-income part of the portfolio, the return was +113.6 percent (compared to +58.7 percent for the Salomon High-Grade Index); for the equities part, the return was +98.7 percent (compared to +83.0 percent for the Dow Jones Industrial Average).

For the first eleven months of 1984, the return on fixed-income assets was +12.1 percent (compared to +14.2 percent for the Salomon Index), on equities -10.0 percent (compared to -1.2 percent for the Dow Jones Industrial Average and -20.7 percent for NASDAQ Industrials), and on the total portfolio -3.3 percent. The disappointing performance in 1984 was concentrated in four Stein Roe mutual funds that accounted for about one-third of the portfolio (and over half the equities). While individual securities in the portfolio outperformed the market averages, the funds concentrate on growth

stocks, the kind that fall more than others during periods when most stocks decline. While these funds hurt performance in 1984, they contributed to performance in past bull markets and are expected to do so in the future.

Stein Roe felt that the stock market as a whole was undervalued. Evidence for this view included the increase in "real" profits (corporate profits after taxes net of inventory gains and underdepreciation of fixed assets) in the past year from an annual rate of \$100 billion to nearly \$200 billion and the decline of the S&P 400 *P/E* ratio to little more than 6, the lowest on a chart going back to 1958. Stein Roe felt that its mutual funds would rise more than the market as a whole.

The Committee decided to change its directive to Stein Roe. The directive formerly specified that equities constitute 50 to 75 percent of the portfolio. The Committee changed the range to 40 to 65 percent. It believed that high interest rates and the tax exempt status of the Association made a shift to more fixed-income assets desirable. The Committee left standing the proviso that Stein Roe need not sell equities if the upper limit is exceeded because of a rise in stock prices.

In previous years, the report of the Finance Committee included a table listing the stocks and fixed dollar assets in the portfolio managed by Stein Roe as of the end of the year. It is being omitted this time. Members wanting a copy of the table can get one by writing to the Treasurer.

RENDIGS FELS, *Chairman*

# Report of the Managing Editor

## *American Economic Review*

I have nothing special to report concerning the operations of the editorial office during 1984.

### Operations

The recent history of manuscript submissions and papers published is shown in Tables 1 and 2. We received 921 papers in 1984, approximately the same number as in 1983. This is the first time in several years that the level of submissions has not increased significantly.

The disposition of manuscripts received during 1983 and 1984 is shown in Table 3. The acceptance rate for 1984 has not changed appreciably since last year.

Our file of accepted papers as of December 31, 1984, contained 109 manuscripts; 32 of these will appear in March 1985, 32 in June, and the remainder in September.

Additional information about editorial office processing lags is provided in Tables 4 and 5. The average inventory of manuscripts "in process" has leveled off during the year; this is a result not of faster reviewing, but rather of the decline in submissions during the year. There has been a slight deterioration since last year in the distribution of editorial decisions lags (Table 4); that is, processing was completed on only 67 percent of manuscripts submitted as compared to 77 percent in 1983.

The subject matter distribution of papers published in 1983 and 1984 is shown in Table 6. It is my impression that the distribution of published papers reflects fairly accurately the distribution of papers submitted; however, our record keeping procedures do not permit me to confirm or disconfirm this conjecture.

**Expenses: Printing and Mailing**

Table 7 shows the printing and mailing expenses for the four regular issues and for the *Papers and Proceedings*, issue of the *Review* for 1984. As in earlier years, the *Papers and Proceedings* accounted for approximately 25 percent of total printing and mailing expenses. There have been only minor changes in costs during the preceding year, and I expect that situation to continue.

TABLE 7—COPIES PRINTED, SIZE, AND COST OF PRINTING AND MAILING, 1984 AER

	Copies Printed	Pages		Cost		
		Net	Gross	Issue	Reprints	Total
March	28,000	267	312	\$48,280.26	\$1,727.01	\$50,007
May	28,000	473	496	72,672.27	2,465.14	75,137
June	27,500	282	304	49,016.74	1,457.65	50,474
September	27,500	332	344	56,538.30	1,605.22	58,144
December <sup>a</sup>	27,500	301	368	58,327.93	1,500.00	59,828
Annual Misc. <sup>b</sup>						8,960
Total		1,655	1,824	\$284,835.50	\$8,755.02	\$302,550

<sup>a</sup> Estimated.<sup>b</sup> Estimated—Based on costs of preparing mailing list, extra shipping charges, and storage costs of back issues.

Accordingly, expenses for 1985 are projected to be much the same as in 1984.

### Papers and Proceedings

The seventh volume of the *Papers and Proceedings* to be prepared by the editorial staff of the *Review* appeared in May 1984. As in 1983, this task was handled by John Riley, the associate editor, and by Wilma St. John and Theresa De Maria. As in 1983, manuscript was processed directly to page proofs for the 1984 *Proceedings*.

### Board of Editors

The Board of Editors now consists of twelve members, chosen by the managing editor with the approval of the Executive Committee of the Association. As in earlier years, the Board has been helpful in dealing with comments on published articles and in reading papers that are the subject of complaint over the fairness or competence of referees. I am grateful to members of the Board for their assistance and advice, for their generally supportive attitude, and for useful criticism of particular actions of the managing editor or particular aspects of the operations of the *Review*.

Six members of the present Board will complete their terms as of March 31, 1985: George Akerlof, Patricia Danzon, Jack Hirshleifer, Rick Mishkin, Sherwin Rosen,

and Richard Schmalensee. I am most grateful to each of them. I also want to thank the continuing members of the Board for services performed and in prospect: Clive Bull, Michael Darby, Philip Graves, Meir Kohn, Susan Woodward, and Leslie Young.

### Appointment of New Managing Editor

In the spring of 1985 I shall be completing my fifth and final year as managing editor. Orley Ashenfelter has accepted the invitation of the Executive Committee to serve as the new managing editor. Under his leadership, there will be three co-editors who will share in the responsibility of final decisions on manuscripts. Given the lag between acceptance and publication, the first manuscripts to be accepted under the new regime should appear in June or September of 1986.

### Acknowledgements

I wish to thank the associate editor, John Riley, and my office associates, Wilma St. John, Theresa De Maria, Marcus Hennessy, and Beverly Bardi for dedicated performance that is frequently beyond the call of duty. My thanks also to our graduate mathematics consultants Fred Luk and Mario Rui Pascoa. Finally, and most wholeheartedly, I want to express my gratitude to the many referees who have devoted so much time and energy to the advancement of our science.

ROBERT W. CLOWER, *Managing Editor*

## Report of the Managing Editor

### *Journal of Economic Literature*

The *Journal of Economic Literature* consists of seven departments. These include the Articles and Book Reviews, which are edited in the Stanford office, and five bibliographic departments, which are edited in the Pittsburgh office. The latter include the basic Subject Index of the articles published in over 270 economics journals, as well as an Author Index and Abstracts of articles from many journals. The Pittsburgh office also edits the annual *Index of Economic Articles* which provides annual cumulations of the subject and author indexes of articles carried in the *Journal* itself (by year of publication in the originating journal), as well as articles published in many collective volumes such as conference proceedings, *festschriften*, and the like. Since 1983, the contents of the annual *Indexes*, brought up to date quarterly, have also been available by computer through the DIALOG Information Retrieval Service. A Note describing the mode of computer access through DIALOG to articles in the *JEL* subject index and the *Index of Economic Articles* appears in each issue of the *Journal* immediately following the Table of Contents.

The Managing Editor edits the Articles department with the help of Associate Editor John Pencavel, and the Book Review department with the help of Associate Editor Alexander Field. The Assistant Editor in the Stanford office is Anne R. Saldich.

During 1984, the Articles department carried twelve major articles as well as Notes and Communications. The Book Review department published 148 reviews.

The *Journal* again refers readers to the statement of its editorial objectives and policies which appeared in an Editor's Note in the June 1981 issue, page 491. In accordance with these policies, the managing editor commissions the *Journal's* expository, survey and review articles and its book reviews. But the *Journal* welcomes proposals for articles.

With the resignation of Naomi Perlman during the past year, supervision of the Pittsburgh office passed to Drucilla Ekwurzel, who had been Assistant Editor for some years and has now been named Associate Editor. Mrs. Ekwurzel works in association with Professor Asatoshi Maeshiro of the University of Pittsburgh, who serves as Editorial Consultant with general responsibility for the classification of articles on which the *Journal's* subject index depends.

I am glad to report that the bibliographical services of the *Journal* have prospered and expanded under the new editorial team. During the past year, the *JEL* has added 17 journals to the approximately 270 whose contents are classified and indexed. The number of abstracts of articles has also increased. The 1979 volume of the *Index of Economic Articles* was published in November. A program of work has now been instituted that will produce two volumes of the *Index* during 1985 and thereafter. This program of accelerated publication will continue through 1987 when the lag in publication of the annual *Index* will have been reduced to the technical minimum, about 18 months. The material available by computer through DIALOG was also enlarged during the past year by the addition of abstracts of articles. A brochure describing the bibliographical search capabilities of DIALOG and the procedures for gaining access to its *Economic Literature Index* (DIALOG file 139) was made available at the registration desk of the 1984 AEA meeting. We also plan to include this brochure in an early mailing to the Association membership.

The great expansion in the number of journals indexed by *JEL* and the considerable number of new journals appearing each year have made it imperative to put our methods of selecting journals for inclusion in the *JEL* indexes on a better basis. As things now stand, it is difficult to add the many new journals to the indexed list. At the same

time, the question arises whether articles in all the journals now indexed are sufficiently valuable to merit inclusion. We are, therefore, in course of making a systematic survey of the journals now indexed. Our list of journals has been classified by field. Panels of economists who are specialists in these fields have been asked to review the journals in their own fields. They are asked to say which of the listed journals, if any, should be dropped, which journals not now listed might be added, and to give the *Journal* their opinions on a number of matters of general policy. Our survey has so far dealt with journals published in English, and the Editorial Board will use the responses to reevaluate the *Journal's* list. Professor Maeshiro took the principal part in preparing the survey and in compiling and analyzing the responses. A similar survey of journals published in languages other than English is now being made.

On behalf of the Association, I should like to express my warm thanks to the 1984 Board of Editors, who helped plan and review the *Journal's* articles, and to the many economists who served as referees both of proposals and drafts. I acknowledge with special thanks the contributions of the following Board members who completed their terms this year: Edwin Burmeister, Edward M. Gramlich, Sherman Robinson, and E. Roy Weintraub.

Ann G. Vollmer and Anita Makler continued on the *Journal* staff at Stanford throughout 1984. Lyndis Rankin continued with larger responsibilities in Pittsburgh. Patricia Andrews and Elizabeth Thornton joined the Pittsburgh staff early in the year. The *Journal* is grateful for their devoted and effective work.

MOSES ABRAMOVITZ, *Managing Editor*

## Report of the Director

### *Job Openings for Economists*

The number of new jobs listed this year increased 15 percent over last year. This interrupted a three-year decline. In 1983, 1,489 new vacancies were advertised; this year 1,718 new jobs were listed. Both academic and nonacademic listings increased although the percentage increase in non-

academic jobs was greater. Table 1 shows total listings (employers), total jobs, new listings, and new jobs by type (academic or nonacademic) for each issue of *JOE* in 1984.

Universities with graduate programs and four-year colleges continue to be the major sources of job listings. Together they con-

stitute about 80 percent of total employers. Table 2 shows the number of employers by type for each 1984 issue.

The field of specialization most in demand continues to be general economic theory. Generalists with a strong background in mathematics and statistics appear to be the type of economist that employers are seeking. The applied area of specialization seems to be of secondary importance. Table 3 shows the number of citations by field of specializa-

tion. General economic theory (000) led, followed by monetary and fiscal (300) and econometrics and statistics (200). This pattern has prevailed for the past several years.

Violet Sikes is almost solely responsible for the publication and distribution of *JOE*. I wish to express my great gratitude for the excellent job she continues to do.

C. ELTON HINSHAW, *Director*

## Report of the Census Advisory Committee

This past year the Bureau of the Census implemented important changes in how it utilizes its advisory committees. These changes were adopted in order to reduce duplication of effort by Bureau personnel, and to improve the efficiency and quality of the advice it obtains from its professional advisory committees.

Previously, Bureau personnel met with the various advisory committees on separate dates. In many instances the same briefings were repeated on these separate occasions. Beginning in the spring of 1984, the Bureau started scheduling joint meetings of the Census Advisory Committees of the American Economic Association, the American Marketing Association, the American Statistical Association, and of the Committee on Population Statistics. These committees participate in a joint, plenary session on the morning of the first day of a two-day meeting. For the remainder of the meeting, the

individual advisory committees meet separately or jointly with one or more advisory committees to discuss topics that are more narrowly focused.

In order to bring about greater involvement of the individual committee members and to help focus the discussion, individual committee members are now asked to serve as formal discussants of the briefing papers presented by Bureau personnel. While this had been common practice in other advisory committees, this arrangement had not been followed by the AEA Census Advisory Committee.

Because of budget limitations coupled with a desire to add four new advisory committees for the 1990 Census, the membership on the AEA committee is being reduced through attrition from fifteen members to nine members.

RICHARD E. QUANDT, *Chairman*

## Report of the Representative to the National Bureau of Economic Research

The National Bureau of Economic Research conducts analyses on a large variety of economic issues; publishes books, working papers, and two periodicals; sponsors conferences; and holds workshops and seminars as part of an annual summer institute. Approximately 269 economists at universities across the United States contribute to the NBER's working paper series, and many other economists, here and abroad, attend conferences and the summer institute.

*Programs.* The NBER's research is organized into eight programs (directors in parentheses): Economic Fluctuations (Robert Hall), Financial Markets and Monetary Economics (Benjamin Friedman), International Studies (William Branson), Labor Studies (Richard Freeman), Taxation (David Bradford), Development of the American Economy (Robert Fogel), Health Economics (Victor Fuchs and Michael Grossman), and Productivity and Technical Change (Zvi Griliches). Program meetings are generally held twice during the academic year, and once, for a longer period, during the summer institute. Over 200 people attended summer institute meetings in Cambridge in 1984.

*Projects.* The NBER also sponsors large-scale projects which bring together researchers from several of these programs. John Shoven is overall director of the Bureau's pensions project. David Wise is directing a major study of the effects of pensions on labor market and retirement decisions.

Another major project, centering on the role of Government Budget and the Private Economy, consists of major efforts in the following areas: the impact of taxation on such behavior as charitable contributions (directed by Charles Clotfelter); measuring and analyzing the role of state and local government in the economy (directed by Harvey Rosen); studies of the compensation of public sector employees (directed by David Wise); and the impact of public sector unionization (directed by Richard Freeman);

and an analysis of government debt and deficits and their impact on the private sector (directed by David Bradford and Benjamin Friedman).

A third project, Productivity and Industrial Change in the World Economy, likewise has several major parts. William Branson and J. David Richardson are directing a project on international economic policy. Research on trade relations and trade policy is directed by Robert Baldwin. Richard Marston leads a group studying international macroeconomic coordination. Colin Bradford is directing a study of trade relations with Asian countries. Jacob Frenkel is directing research on exchange rates.

*Conferences.* In 1984, the NBER sponsored conferences (organizers in parentheses) in the United States and abroad on the following topics: Global Implications of the Trade Patterns of East and Southeast Asia (William Branson and Colin Bradford); Economics of Trade Policy (Robert Baldwin, William Branson, and J. David Richardson); Business Cycles (Robert Gordon); Pensions and Retirement in the United States (John Shoven); State and Local Public Finance (Harvey Rosen); International Seminar on Macroeconomics (Georges de Menil and Robert Gordon); International Coordination of Economic Policy (Willem Buiter and Richard Marston); Corporate Capital Structures in the United States (Benjamin Friedman); Public Sector Payrolls (David Wise); and Structural Adjustment and the Real Exchange in Developing Countries (Sebastian Edwards and William Branson); Long-Term Factors in American Economic Growth (Stanley Engerman and Robert Gallman).

*Books.* In 1984, the following NBER books were published by the University of Chicago Press: *R&D, Patents, and Productivity* (Zvi Griliches, ed.); *Economic Transfers in the United States* (Marilyn Moon, ed.); *A Retrospective on the classical Gold Standard, 1821–1931* (Michael D. Bordo and Anna J. Schwartz, eds.); *The Structure and Evolu-*

*tion of Recent U.S. Trade Policy* (Robert E. Baldwin and Anne O. Krueger, eds.); *Exchange Rate Theory and Practice* (John F. Bilson and Richard C. Marston, eds.).

In addition, Harvard University Press published *Economics of Worldwide Stagflation* (Michael Bruno and Jeffrey D. Sachs).

In 1985, the following NBER books will be published: *Social Experimentation* (Jerry A. Hausman and David A. Wise, eds.); *Corporate Capital Structures in the United States* (Benjamin M. Friedman, ed.); *Federal Tax Policy and Charitable Giving* (Charles T. Clotfelter); *A General Equilibrium Model for Tax Policy Evaluation* (Charles L. Ballard, Don Fullerton, John B. Shoven, and John Whalley); *Pensions, Labor, and Individual Choice* (David A. Wise, ed.); *Horizontal Equity, Uncertainty, and Measures of Well-Being* (Martin David and Timothy Smeeding, eds.); *Monitoring Business Cycles in Market-Oriented Countries: Developing and Using International Economic Indicators* (Philip A. Klein and Geoffrey H. Moore).

*Periodicals.* The NBER publishes two peri-

odicals, the *Digest* and the *Reporter*. The *Digest* provides four summaries each month on recent NBER working papers of general interest. The quarterly *Reporter* contains longer summaries of recent program activity, reports of NBER conferences, reviews of recent work by NBER researchers, and abstracts of working papers issued during the previous quarter.

During 1984 Martin Feldstein replaced Eli Shapiro as President of NBER and Geoffrey Carliner replaced David Hartman as Executive Director.

Further information about the NBER is available in NBER publications, from Geoffrey Carliner at NBER, 1050 Massachusetts Avenue, Cambridge, MA 02138, or from the undersigned at Johns Hopkins University, Baltimore, MD 21218.

I am happy to acknowledge Geoffrey Carliner's major contribution to the preparation of this report.

CARL F. CHRIST, *Representative*

## Policy and Advisory Board of the Economics Institute

The year 1984 was a year of recovery and adjustment for the Economics Institute, as it was for the developing countries, from which most of the Institute's students and revenues come.

Total enrollments were up in 1984, following a substantial drop in 1983. The 1984 enrollment was about 1350 students (in 5-week-term student equivalents), about 40 percent each during spring and summer terms, and 20 percent during fall terms.

Staff and administrative stability have benefitted greatly in recent years by the Institute's year-round program. A major innovation in 1983 and 1984 was the operation of pre-Institute training programs in Indonesia. This experiment enabled both the Institute and the sponsors to learn a great deal about operation and administration of such programs, and enabled the Institute to maintain its staff during the recession.

The Institute continues to draw students from throughout the developing countries. The major limitation on its ability to draw large numbers of students from the poorest countries is its need to finance nearly its full costs from tuition and fees, and its corresponding ability to offer only small scholarship assistance. Raising scholarship funds is the Institute's highest priority.

The Board held its annual meeting November 16 and 17, 1984, in Boulder, Colorado. Several Board members also visited the Institute during the summer of 1984. During 1984, Stefan Roback and Lance Davis joined the Board.

EDWIN S. MILLS, *Chairman*

## Report of the Representative to the U.S. National Commission for UNESCO

During 1984, the attention of the U.S. National Commission for UNESCO was dominated by the decision of the U.S. government, announced on December 29, 1983, to withdraw from the organization at the end of 1984. This decision was subject to reconsideration if the practices and administration of UNESCO to which the United States has vigorously objected were significantly changed for the better. The Commission, which consists of private citizens, had earlier expressed general agreement with many or most of the government's criticisms of UNESCO but disagreed with the decision to withdraw, supporting continued U.S. participation largely because it thought the United States in a better position to exert influence toward the needed reforms from inside the organization than from outside it.

As part of the Commission's effort to assist in obtaining the needed reforms and also to observe how far UNESCO was responding to U.S. pressure for those reforms and to observe the attitudes of other member countries toward the U.S. position, six Commissioners attended the meeting of UNESCO's Executive Board in September and October, 1984. The co-chairpersons of this delegation reported to the Commission at its forty-eighth meeting on December 13 that most member countries had become concerned that the United States would withdraw at the end of 1984, irrespective of what changes the organization made during the year. "Most of our allies believed that necessary reforms—many of which they also seek—can best be gained by working from within the organization." By withdrawing, the Commission's observers said, the United States would lose a permanent seat in the agency's Executive Board, would lose leverage, would have less opportunity to influence development of the UNESCO programs that would be in effect in the medium-term future, and would lose a major role in selecting the next Director-General. The number of Americans in the

professional staff would also gradually decline.

This view was the opposite of that expressed by a Monitoring Panel appointed by Secretary of State Shultz to monitor the extent of change in the activities of and within UNESCO during 1984, especially in the subjects of greatest concern to the United States: that the interests of "minority groups of countries," which provide most of the financing, are inadequately protected; that UNESCO has deviated from its original purposes; that in solving problems it has adopted an excessively "statist" approach, as opposed to a "Western" approach; and that it is mismanaged, especially as regards its budget. This Monitoring Panel reported to the Secretary of State in late November that although there was considerable discussion and some progress, there was no "concrete" change.

The U.S. government stated its position and concerns regarding UNESCO's draft program and budget for 1986-87 in a July letter to Director-General M'Bow. It expressed desire for an increase in the authority of the member states by strengthening the General Conference and, in particular, the Executive Board; creation of a mechanism to ensure that major decision and programs have the support of all geographic groups, included the one that pays most of UNESCO's budget; return to concentration on UNESCO's core areas; changes in budget and management; and decentralization of power within the Secretariat.

Following discussion at the Commission's meeting of the proposed and evidently imminent actual U.S. withdrawal, one of the Commissioners circulated a proposed resolution "that it is not in the best interest of the United States to continue to participate and fund educational, scientific and cultural activities through membership in UNESCO," the Commission endorses President Reagan's decision to withdraw U.S. membership, fund-

ing, and support from UNESCO, and requests that the U.S. Congress disband the U.S. National Commission for UNESCO. This resolution was not acted upon. It gave way to a compromise resolution which stated that the U.S. notice of withdrawal had launched a process of reform in UNESCO, reaffirmed the Commission's conclusion that membership in UNESCO is in the U.S. national interest. It also recommended that if the United States withdraws, it should cooperate with the Director-General and other member states to encourage reforms that would permit the United States to rejoin the agency, and that the U.S. government involve representatives of the private sector in the effort to obtain such reforms. This resolution, with some amendments, passed by a vote of 37 (including your representative's vote) in favor to 9 against.

Withdrawal of the United States from UNESCO naturally would raise the question of the future of the U.S. National Commission. It was argued, on the one hand, that since the United States, in announcing that it would withdraw from UNESCO because of objections to its policies and administrative practices and procedures, expressed an intention to return to it if reforms removed those objections, continuation of the Commission

was desirable so it could advise the U.S. government as to whether reforms were sufficient, keep the private sector informed about UNESCO, and act as liaison between the private sector, UNESCO, and other national commissions. Further, if the United States later resumed membership in UNESCO, an advisory commission would again be needed and it would be better to retain the existing mechanism in some form than to abolish it and then have to recreate one. Against these arguments, it was argued that if the United States ceased to belong to UNESCO, the U.S. government did not need a body to advise it regarding its policies toward that agency; the Commission would cease to have grounds for continued existence. A resolution approved by the Executive Commission was offered stating that the Commission has an "especially important mission in the period ahead," and recommending that its officers and Executive Commission continue to press for official support, restoration of adequate funding and staff during "this transitional phase," and "remain seized of all questions related to the future of the National Commission." This resolution passed by a vote of 35 to 9 votes.

WALTER S. SALANT, *Representative*

## The Committee on the Status of Women in the Economics Profession

Women continue to increase their representation in the economics profession, but the rapid entry of young women occurring in other elite professions is not yet evident in economics. In 1983-84, the group of economics departments that grant most of the Ph.D.s (the so-called Chairs' Group) reported that 16 percent of their doctorates went to women. While this is an advance from the levels of the 1970's, it is below the proportion of women among newly trained lawyers (32 percent in 1980-81), physicians (25 percent), and chemical engineers (19 percent). Among undergraduates, the proportion of mathematics majors who are women (43 percent) exceeds the proportion of economics majors who are women (32 percent).

The economics profession continues to appear to undergraduate students as inhospitable to women. While the President-elect and one of the two Vice Presidents of the American Economic Association are currently women, the undergraduate is influenced by what she sees on her own campus. Surely a major factor in the perpetuation of this inhospitable image in the minds of today's students is the fact that many academic departments continue to be 100 percent male in their senior ranks. Some departments are 100 percent male in their entirety. In 1983-84, the situation with respect to the senior ranked positions was

	Number of departments	Number of women above rank of Asst. Prof.	At least this many departments with no women above Asst. Prof.:
Chairs' Group	41	22	19
Other Ph.D. granting depts.	34	21	13
Depts. granting MA only	46	27	19
Depts. granting BA only	189	49	140

The 41 departments of the Chairs' Group who reported on the composition of their faculties to the annual American Economic

Association survey, employed altogether 22 women as Full Professor or Associate Professor. We can deduce from this that at least 19, and surely more than half of them, had not a single woman above the rank of Assistant Professor.

Promotions for women within departments are less frequent than for men, given their representation in junior faculty positions (see Table 1). What is perhaps just as damaging is the fact that the ability of women to move from one school to a senior position in another school appears to be virtually nil. Of the 34 economists hired for senior positions by the departments of the Chairs' Group; only one was a woman. In all departments throughout the country, only two women made such a move.

In part to promote the visibility of women economists already in academic positions, CSWEP compiles and publishes a list of women faculty members at institutions which grant graduate degrees in economics. The women economists on that list should be prime candidates for recruitment by other academic departments. In the coming year, we will continue to update this list, so that it will be of greater use to economics departments who want to recruit women to their senior positions. Another project currently under examination for feasibility is the publication of a bibliography of women economists' scholarly publications, based on the *Journal of Economic Literature*.

We also plan to begin compiling lists of departments with no women faculty on senior levels or no women faculty at any level. In future years those lists should grow shorter and shorter, as more and more departments implement plans to end their exclusively male composition.

### Few Women Researchers Affiliated with the National Bureau

One of the most important functions of CSWEP is to campaign for the inclusion of

women economists in all of the important activities in which professional economists are engaged. For almost a decade, the leadership of CSWEP has been particularly concerned with the situation at the National Bureau of Economic Research, where women have been largely excluded. On November 20, 1984, the present Chair of CSWEP and the two previous Chairs (Elizabeth Bailey, Dean, Graduate School of Industrial Administration, Carnegie-Mellon University, and Ann Friedlaender, Dean and Professor of Economics, Massachusetts Institute of Technology) signed a long letter to NBER President Martin Feldstein. In part, the letter said:

We at CSWEP are concerned about the low level of representation of wom-

en in the activities of the NBER. Currently only 6 of 170 Bureau research associates are women (2.8%), a level which has not shown any tendency to increase over the years since you became President. Yet the Bureau conducts research in a number of fields of applied economics in which women economists are active. We are concerned that the Bureau's low representation of women, combined with its steadily growing size and command over research funds, is increasingly putting younger women economists at a disadvantage relative to male economists in the same fields who have Bureau affiliations. We would like to urge you to take concrete measures to change this situation and we want to provide whatever help and guidance we can.

Note: See Table 1.

Obviously, membership in one of the NBER's permanent research programs provides tremendous benefits to younger academics.... Despite the substantial benefit from belonging to one of these programs, there appears to be no formal selection procedure that would ensure that the best researchers in each field are represented. Most research associates/fellows appear to be either former students of directors or senior research associates of that group or junior faculty at a few leading universities. Apparently no attempt is made to publicize these positions or to allow outsiders to apply. Due to the extent that women are not part of the "old-boy network" linking the Bureau research associates, they are effectively eliminated from the pool of potential associates....

What can be done to remedy this situation? We have several suggestions.

First, many male economists were brought into Bureau association because they were either Ph.D. students of Bureau project directors (or other Bureau research associates) or were junior faculty members in the University departments where Bureau project directors teach. Therefore, one way that we advocate for bringing in more women researchers is for all NBER project directors and research associates to review their Ph.D. students of the last

five years and the recent women hires in their departments and to consider bringing in any interested and qualified women economists who have been passed over. If, on the other hand, on doing this they find that they have had no women Ph.D. students over the past five years, then perhaps they should ask themselves why not and consider seriously whether they have been practicing unconscious sex discrimination in selection of thesis students....

Second, some procedure should be set up to allow "outsiders" to apply for positions as NBER research fellows in each group. Since the group of research associates/research fellows is by invitation only, it provides little opportunity for women to gain entry, since the NBER's project directors and other senior researchers have been very unlikely in the past to bring them in. This means that women economists are likely to be excluded by virtue of the selection process even if they are part of the pool of distinguished economists working in areas of interest to the Bureau.

We await your reply and, again, offer our help and guidance as you consider what concrete measures would be best adopted to rectify this situation.

Sincerely,

...

### Representation at Annual Meetings

Any process of professional selection that is informal, and whose details are only known or understood by a relatively small in-group,

are disadvantageous to women, who benefit less frequently than men from sponsorship by more established members of the profession. The process by which sessions at the AEA annual meetings are organized and

papers invited has been one of these little-understood processes. Formally speaking, the President-elect does the inviting; in practice, many volunteers communicate to him or her their desire to participate, and it is out of these submissions that a considerable part of the program is in fact assembled with the help of referees.

We at CSWEP will continue to urge that the selection procedures for the annual meetings be made more formal and more public. While there is an understandable interest in having the profession's (mostly male) celebrities on parade at the meetings, we would urge procedures which give a better representation to innovative research from the less well-connected members of the profession, women among them. In the meantime, through our *Newsletter* we are urging women economists to submit proposals for sessions or individual papers to the President-elect.

#### Research on Gender-Related Topics

CSWEP has been concerned to encourage and foster research on gender roles in the economy and related policy issues, and to make sure that women economists and points of view sensitive to the special problems many women face under current economic institutions are well represented in the field.

To this end, we continue to sponsor sessions on these topics at the AEA and regional meetings. In November 1984, CSWEP jointly with The Brookings Institution sponsored a conference on Gender Issues in the Workplace, arranged by Clair Brown and Joseph Pechman.

As research proceeds and interest rises, courses on the economics of gender roles are being offered at an increasing number of schools. At least three new textbooks are in the works. A number of economics departments are specifically looking to recruit a specialist in gender-related topics, and individual economists are "coming out" as specialists in the field.

#### Committee Operation

We wish to thank Gail Wilensky and Nancy Ruggles, whose terms on the Committee expires this year. Gratitude is also due to Aleta Styers, who continues to bear the time-consuming editorial duties on the *Newsletter* with relative fortitude, and to Joan Haworth, who served as Membership Secretary. New Committee members for 1985 are Helen Junz of the IMF and Karen Davis of the Johns Hopkins School of Public Health.

BARBARA R. BERGMANN, *Chair*

## Report of the Committee on U.S.–China Exchanges

As the reports of our Committee in the last three years reveal, there has been continued and expanding exchange activities between American and Chinese economists. In 1984, a great step was taken by the Chinese government to make post-Marxian modern economics official, in the sense of introducing it to the Chinese university curriculum, side by side with Marxian economics, as being important for China's economic development. Previously, modern economics was taught as an elective for the understanding of capitalist economies only.

To illustrate the change in viewpoint, the Chinese Ministry of Education sponsored a workshop in microeconomics for university teachers, graduate students, and government officials. The workshop was held at Peking University from June 11 to July 21. The lecturers were Sherwin Rosen (micro theory, human capital and labor), Marc Nerlove (micro theory, agricultural supply, and empirical studies), Edwin Mills (development, urban, and environmental economics), and Gregory Chow (applications to China). Microeconomics was to become an important part of economics education in China. Workshops in macroeconomics and econometrics are planned for the summers of 1985 and 1986, respectively.

The Ministry of Education decided to send students abroad to study economics. On November 17–20, TOEFL, mathematics, and economics examinations (given in English, with economics questions provided by Mills, Rosen, and Chow) were administered by the Ministry to 151 candidates who had been carefully selected from twenty-seven major Chinese universities and economics and finance colleges, using scholastic records and preliminary tests. Eighty-one candidates, who received a total grade of 120 or higher in mathematics and economics, have been rec-

ommended for graduate work to sixty-one American and Canadian universities, including all major economics departments.

Both the Ministry of Education and the Chinese Academy of Social Sciences (CASS) are seeking financial support to strengthen economics education and research at the universities and economic research institutes. To consider such support, the Ford Foundation has formed a committee, co-chaired by Dwight Perkins and Gregory Chow. Activities to be supported might include workshops, Boulder-like institutes, and research programs in China, fellowships for students and visiting scholars from and to China, joint research projects, and library and computer facilities.

In 1984, many American economists lectured in China. Many Chinese economists visited the United States, including a delegation from CASS in September, mentioned in our Report last year. From 1984 on, many teaching and research opportunities in China are becoming available to American economists. To find a suitable hosting institution, a potential visitor can consult published material such as bulletins of universities and research institutes, and Chinese economics journals reporting on research conducted at various institutions. Helpful information can be found in Teh-wei Hu's research report, "The State of American Economic Studies in the People's Republic of China" (U.S. Information Agency: April 1984) and in Gregory Chow's report, "Economic Research in China" (Princeton University, 1984). Personal contacts will also be useful to generate a suitable visiting arrangement, as in the case of searching for a visiting position in the United States.

GREGORY C. CHOW, *Chair*

## Report of the Committee on Economic Education

The Committee this year (1984) closed out its work on the economics major project which had been directed by John Siegfried, carried out in conjunction with the Joint Council on Economic Education, and financed by the Alfred P. Sloan Foundation. The project resulted in a series of publications that provide benchmark data on the characteristics of economics major programs at the college and university level, and of economics major students enrolled in a subset of these institutions. The data collected in the study are available for further analysis (for information, contact John Sumansky at the Joint Council on Economic Education, 2 Park Avenue, New York, NY 10016).

The Committee is exploring the possibility of convening a small conference to follow up on the study of the economics major. This conference would be concerned with trying to specify more fully what it is that we would like economics majors to be able to do upon graduation. What knowledge and skills might we reasonably expect them to possess? What competencies might we expect them to be able to demonstrate? No unanimity of views about the answers to these questions is anticipated. Nevertheless, it is hoped that the conference and resulting papers would aid departments and sharpen their understanding of what they are attempting to do in educating their majors.

The Committee has also reviewed its principal on-going project, the Teacher Training Program, carried out in collaboration with the Joint Council in Economic Education. The Program, initiated in 1972 with the help of a grant from the Alfred P. Sloan Foundation, led to the institutionalization of teacher training programs for teach-

ing assistants, and in some cases for faculty members at a number of major universities; it also produced a Resource Manual and accompanying video tapes to support these programs. The second phase of this project, supported by the Lilly Endowment Inc., led to the development of an annual one-week seminar designed to help improve the teaching skills of economics faculty members and to help their departments establish their own teacher training programs. The third phase, supported by Citibank and Borg-Warner, funded regional seminars whose purpose was to build a cadre of trainers that would assist still other departments establish their own teacher training programs.

The Committee decided to undertake a thorough evaluation of the TTP program, prepare a new edition of the Resource Manual, and develop a new set of videotapes. The evaluation will be done by Mike Salemi and should be completed within the year. Work on revising the Resource Manual will begin later this year, followed by preparation of the videotapes.

The Committee continues its efforts to build the circulation and quality of the *Journal of Economic Education*. Just a year ago the *Journal's* focus was greatly broadened. Traditionally, it reflected an almost exclusive emphasis on research articles dealing with economic education. Since then its scope has been expanded to include content articles on economics, papers on the teaching of economics, innovations in economic instruction, and information of general interest to the profession.

W. LEE HANSEN, *Chair*

## Report of the *Ad Hoc* Committee on Financial Reporting and Changing Prices

The *Ad Hoc* Committee was set up by the President of the AEA at the request of the Financial Accounting Standards Board to help it reach a decision as to whether the inflation disclosures mandated five years earlier through Statement No. 33, on an experimental basis, should be continued in some form, permanently or experimentally, or should be discontinued.

The Committee submitted a unanimous preliminary report in August 1984 and a final report on December 12, 1984. The full report (copies can be secured upon request to the Chair) reviews a substantial body of evidence on whether the inflation disclosures have provided "valuable" information. It concludes that the evidence is rather negative, both with respect to the use of the information by various market participants and in terms of the association between the information disclosed and the market valuation of equity. It finds, however, that it is not possible from this evidence to establish whether the negative findings reflect: (i) the ability of the market to secure the information from sources other than, and in advance of, the inflation disclosure; or (ii) the poor quality and lack of standardization of the information disclosed; or, finally, (iii) the fact that potential users (wrongly) regard the information as intrinsically worthless.

The report stresses that an understanding of the main reason for the prevailing disre-

gard of the information disclosed under Statement 33 is crucial in deciding whether it is worth continuing such disclosures. Accordingly, it recommends a number of steps designed to probe further into the reason for the puzzling, apparent failure on the part of a variety of potential users to utilize the information, and create conditions for increased future utilization. It further recommends that, while these steps are being implemented, the requirement of some form of inflation disclosures be continued for an experimental period of up to five years.

With respect to revisions in the content of the current disclosures, the Committee submitted two main suggestions. The first relates to the measurement of capital consumption and recommends not dropping the financial capital maintenance concept—as implemented through a general price-level adjustment on long-term assets and shareholders' equity—in favor of a replacement cost (physical capital maintenance) concept. The second recommendation, relating to the inflation adjustment of nominal interest cost, is that the adjustment should be applied not to the book values of assets, as currently required, but rather to the market value, and that it should also include the change, if any, in the market valuation of the debt.

FRANCO MODIGLIANI, *Chair*

# Essential Reading for the Economist

## **The U.S. Economy Demystified**

*What the Major Economic Statistics Mean and Their Significance for Business*

Albert T. Sommers, The Conference Board

Foreword by James T. Mills

"Al Sommers is one of the very few economists in this country who understands the subtle relationships which exist between our data system and the complex economy which it is endeavoring to measure."—Alan Greenspan

"Every academic, business, and government economist concerned with the course of the economy from month to month and year to year has learned to respect the insights of Al Sommers. He knows the numbers thoroughly and interprets them with perception and wisdom, based on his own understanding of the mechanisms at work, born of long experience."—James Tobin

April ISBN 0-669-09427-7 \$16.95

In paper: 0-669-09821-3 \$10.00

## **The Global Financial Structure in Transition**

*Consequences for International Finance and Trade*

Joel McClellan, the Quaker United Nations Program, editor

This book demonstrates the wide diversity of opinions on how to understand and manage the rapidly changing forces in international finance and trade. Topics include international indebtedness, trade deficits, long-term investments, and refinancing and trade expansion.

May ISBN 0-669-09581-8 ca. \$32.00

## **Political Economy and Risk in World Financial Markets**

Tamir Agmon, Tel-Aviv University

The author, an internationally known Israeli economist, presents specific strategies under two broad headings, risk avoidance and risk negotiation. He illustrates these with case studies and a mathematical model describing the changing relations between a multinational corporation and the host government of a newly industrialized country.

June ISBN 0-669-08339-9 ca. \$22.50

## **The Political Economy of Coal**

Ferdinand E. Banks, University of Uppsala and the University of Melbourne

An encyclopedic primer on worldwide energy economics, with a particular emphasis on coal. The author looks at coal production's effect on the world economy and considers how various countries' reserves affect the balance of power.

288 pages ISBN 0-669-06109-7 \$29.00

# *Decision Analysis Takes a Giant Step Down*

Accurate planning and decision making no longer demand expensive main-frame and connect charges. The process requirements have been reduced to:

- IBM PC (minimum 256K)
- DOS 2.0
- OTIS

**OTIS** is a decision-support command language designed to manage time series data for analysis and forecasting. Intuitively easy to use and understand, the system combines into a single program the following features:

*Time series analysis*

*Data and file management*

*Graphics and data display*

*Report generating*

*Command processing*

*Statistical analysis*

*Single equation solving*

*Menu processing*

*Regression analysis*

*Correlation analysis*

*Simultaneous equation  
simulations*

Although stand-alone, **OTIS** is compatible with other popular software programs, such as Lotus 123, Symphony, and dBase.

Time series are developed and managed in a "workspace" (memory) environment. Series can be created and transformed using the usual arithmetic operations, and functions such as square root, logarithm, and exponential. In addition, observations can easily be modified, added to, and deleted from new and existing series. Each series contains a comment to describe its purpose and/or creation. Series may be displayed as listing, character plots and/or line graphs. Equations can be generated for purposes of solving singly or simultaneously. Series, equations, and parameters can be stored and retrieved in disk files which are password protected. Moreover, series can be transferred easily (in ASCII format) between **OTIS** and other popular software programs, such as Lotus 123, Symphony, dBase and Framework.

The program is command driven for analytical speed with "help" reminders available at all times. Ease of use is enhanced by requiring for execution only the first two characters of any command. To facilitate customized applications, **OTIS** also provides a command programming language and menu processor. Finally, commands can be stored and executed from an executable disk file.

New titles from  
**The National Bureau of Economic Research:**

**The Structure  
and Evolution of  
Recent U.S. Trade Policy**

*Edited by Robert E. Baldwin and  
Anne O. Krueger*

This volume represents the first systematic effort to analyze specific U.S. trade policies, particularly nontariff measures. It provides a better understanding of how trade policies operate, of how effective they are, and of their costs and benefits to trading nations.

**An NBER Conference Report**  
Cloth \$50.00 448 pages

**Exchange Rate  
Theory and Practice**

*Edited by John F. O. Bilson and  
Richard C. Marston*

Here the world's most respected international monetary economists discuss three significant new approaches to the economics of exchange rates, test and question these approaches with evidence from empirical studies, and analyze a number of exchange rate policies in use today, including the European Monetary System.

**An NBER Conference Report**  
Cloth \$58.00 544 pages

**A Retrospective on the  
Classical Gold Standard,  
1821–1931**

*Edited by Michael D. Bordo and  
Anna J. Schwartz*

The studies in this volume were designed to gain a better understanding of the historical gold standard, but they also throw light on the question of whether restoring it today could help cure inflation, high interest rates, and low productivity growth.

**An NBER Conference Report**  
Cloth \$65.00 694 pages

**Economic Transfers  
in the United States**

*Edited by Marilyn Moon*

In recent years the definition of an economic transfer — a payment to an individual or institution that does not arise out of current productive activity — has been subject to ever wider interpretation. This volume addresses that trend and introduces new methods of measuring transfers in the American economy. Researchers, policy analysts, and those who compile statistics on which social programs are based will value the diverse approaches of these ten papers and their accompanying comments.

**Robert J. Barro**  
*University of Rochester*  
**MACROECONOMICS**

Barro's Macroeconomics is the first modern presentation of the market clearing approach to macroeconomics. It provides an honest and realistic alternative to the cumbersome and unrewarding IS/LM approach of current intermediate texts.

"Robert Barro has been a leading contributor to recent developments in the analysis of the overall behavior of the economy. He has now written a lucid, comprehensive, and authoritative exposition of the current state of our understanding of these phenomena. His text covers both the latest theoretical developments and the latest empirical evidence. It can be highly recommended on both levels."

—Milton Friedman,  
Senior Research Fellow  
Hoover Institution on War, Revolution and Peace,  
Stanford University

"... What Barro does is not only build a macroeconomic model from the ground up but also one that is meant to explain observed economic phenomena... if only other textbook authors would try harder to do this, students would learn more and teachers would find their job much easier."

—James Barth,  
The George Washington University

1984     580 pp.

# AEA sponsored Group Life Insurance for you and your family— at attractive rates!

The AEA Group Life Insurance Plan can help provide valuable supplementary protection—at attractive rates—for eligible members and their dependents.

Because AEA participates in a large Insurance Trust which includes other scientific and technical organizations, the low cost may be even further reduced by premium credits. In the past eight years, insured members received credits on their April 1 semiannual payment notices averaging over 44% of their annual premium contributions. (These credits are based on the amount paid during the previous policy year ending September 30.) Of course future premium credits, and their amounts, cannot be promised or guaranteed.

Now may be a good time for you to re-evaluate your present coverage and look into AEA Life Insurance. Just fill out and return the coupon for more details at no obligation.

# Software for Hard Problems.

If you've outgrown your spreadsheet, if you're tired of waiting for the mainframe, consider STATA.<sup>™</sup>

- Like a spreadsheet program, STATA<sup>™</sup> is interactive. STATA<sup>™</sup> makes it easy to answer the "what if" questions that spreadsheet programs handle so well.
- Like a database management program, STATA<sup>™</sup> allows you to create complex data sets, transform them in almost any way you desire, make tables, and locate particular pieces of information.
- Like a statistical package, STATA<sup>™</sup> performs a variety of statistical analyses including multivariate regression.
- Like a programming language, STATA<sup>™</sup> allows you to store groups of STATA<sup>™</sup> commands so that complicated analyses can be automated.

And when you think your problem has outgrown your PC, think again. STATA<sup>™</sup> is the software for hard problems.

STATA<sup>™</sup> efficiently sorts, appends, and merges datasets. STATA<sup>™</sup> understands many different data formats (for example, STATA<sup>™</sup> can read Census data directly). STATA<sup>™</sup> can also format data for use by other programs. STATA<sup>™</sup> can encrypt data to keep private data private.

STATA<sup>™</sup> calculates all the standard univariate statistics, correlations and covariances, one-, two-, and n-way tables with chi-square tests for independence. STATA<sup>™</sup> estimates multivariate regression and ANOVA models on an unlimited

number of observations using ordinary least squares, instrumental variables, or two-stage least squares. STATA<sup>™</sup> also performs tests of linear hypotheses about these models. You can perform simulations and Monte Carlo studies using STATA's prediction and random number functions.

STATA<sup>™</sup> labels your variables and their values so that your output is as close to publication-ready as possible. STATA<sup>™</sup> makes tables and plots and can copy its output to a file that can be edited with your word processor.

All of this is available for the IBM PC, PC/XT, or PC/AT with 256K of memory and one double-sided disk drive, for \$395.

A demonstration diskette is \$15.00, and the payment can be applied to subsequent purchase. For more information, call us at (213) 470-4341 or write to us at: Computing Resource Center, 10801 National Boulevard, Los Angeles, California 90064. Academic and quantity discounts available.

# **The Journal of International Economics and Economic Integration Offers**

## **\$5,000**

### **For the First Annual Daeyang Prize in Economics**

- The Journal of International Economics and Economic Integration is published biannually by the Institute for International Economics, King Sejong University, Seoul, Korea.
- The purpose of the Journal of International Economics and Economic Integration is to support and encourage research in the area of international trade, international finance and other related economic issues that include general professional interest in international economic affairs.
- The Journal of International Economics and Economic Integration welcomes unsolicited manuscripts, which will be considered for publication by the Editorial Board.
- The Editorial Board will choose fourteen manuscripts for publication on an annual basis.
- The Editorial Board will choose the best manuscript out of the fourteen to be awarded the \$5,000 Daeyang Prize in Economics.
- The manuscripts, which should be accompanied by an abstract of no more than 100 words, should be typewritten, double-spaced, in English with footnotes, references, figures, tables and any other illustrative material on separate sheets.
- Three copies of the manuscript and all accompanying material should be submitted to the following address by October 31, 1985 for consideration for the 1986 publication.

**Institute for International Economics  
King Sejong University  
Seongdong-Ku, Seoul, Korea**

## ***Economics of Worldwide Stagflation***

*Michael Bruno and Jeffrey Sachs*

"This is *serious* supply-side economics . . . An excellent and important book."—Robert M. Solow

\$25.00

## ***Racial Conflict and Economic Development***

*W. Arthur Lewis*

Lewis discerns the ways in which race and economics affect individuals and groups, bringing a personal viewpoint to the problems faced by both less-developed and more-developed countries.

*The W. E. B. Du Bois Lectures*

\$12.50

## ***Tax Expenditures***

*Stanley S. Surrey and Paul R. McDaniel*

"This book is comprehensive, challenging, and constructive, and it fills a big void in the tax literature. It will interest economists, political scientists, lawyers, accountants, and legislators."—Joseph Pechman

\$27.50

## ***Housing and Neighborhood Dynamics***

*A Simulation Study*

*John F. Kain and William C. Apgar, Jr.*

Using the Harvard Urban Development Simulation Model, the authors assess the effects of programs that provide direct assistance to low-income property owners in an attempt to arrest neighborhood decline and encourage revitalization.

*Harvard Economic Studies*, 157

\$27.50

## ***Family Firm to Modern Multinational***

*Norton Company, a New England Enterprise*

*Charles W. Cheape*

The history of Norton Company, so carefully detailed here from company records and interviews, illustrates both the continuity and change important in the evolution of large-scale business in the United States.

*Harvard Studies in Business History*, 36

\$25.00

## ***Equality in America***

*The View from the Top*

*Sidney Verba and Gary Orren*

Based on a study of leaders from all significant sectors of American society, this book examines American attitudes toward equality by placing those beliefs in historical context and demonstrating a relationship between political and economic equality.

\$25.00 cloth; \$12.50 paper

## ***Tax Revolt***

*Something for Nothing in California*

*Enlarged Edition*

*David O. Sears and Jack Citrin*

"This book is the first substantial study of the California tax revolt. It is well crafted and well written and has great depth and sophistication. The topic is of intense interest and importance . . . A significant work."—Walter Dean Burnham

\$9.95 paper

## ***A Treatise on the Family***

*Gary S. Becker*

"This truly pathbreaking book marries techniques and problems hitherto regarded as utterly incompatible—rigorous economic reasoning to understanding the family. The marriage is astoundingly productive. It is destined to affect the foundations of every science dealing with human behavior."—Milton Friedman

## **The Economics of Oil Crisis**

Theories of Oil Crisis, Oil Rent and Internationalization of  
Capital in the Oil Industry

Cyrus Bina

In this in-depth study of the causes and consequences of the 1972 crisis, the author, a former financial analyst with the treasury department of Iran, rejects the traditional theory that the large price jumps resulted from voluntary actions taken by OPEC and other Third World nations. He argues instead that it was actually the economics of domestic oil production in the continental United States that generated the huge price spiral.

1985

268 pp.

ISBN 0-312-23661-1

\$29.95

## **The Economic Theory of Multinational Enterprise**

Selected Papers

*Peter J. Buckley and Mark Casson*

Basing their approach on the internalization rubric and least cost location, the authors compare the economics theory of the multinational enterprise with alternative theories, presenting an authoritative review of the evidence that emerges, discuss alternatives to the multinational, including multiplant firms and cartels, examine the aspects of MNE behavior found to be common to all modes of international technology transfer, present a detailed modelling of the location decisions of MNEs, discuss the influence of financial and organizational factors, and integrate the concept of entrepreneurship into the theory, stressing the importance of flows of information and intermediate products.

1985

235 pp.

ISBN 0-312-23636-0

\$27.50

## **Free Market Economics**

A Critical Appraisal

*Andrew Schotter*

Schotter examines the theoretical bases of competitive economics, characterizing the free market economic argument, its basic assumptions and their roots in economic thought. He further presents criticisms of this argument, raising doubts about the blind advocacy of free market solutions to current social problems, and applies these criticisms to an analysis of public policy issues including minimum wage, affirmative action, crime and welfare, and the rational expectations debate. **"A clear, logical and penetrating analysis."**—*Choice*

1984

147 pp.

ISBN 0-312-30369-6

\$22.50

## **Full Employment Without Inflation**

Manifesto for a Governed Economy

*Tim Hazledine*

In this provocative study, the author develops an original reformulation of government's role in policy which, he contends, will lead to a stable and sensible economic environment. The issues discussed include the failure of Keynesianism and Monetarism, principles of elasticity and policy instruments, price controls, trade and exchange rates, deficits, monopoly, the labor force, and industrial, energy and environmental policy.

1984

264 pp.

ISBN 0-312-30971-6

\$27.50

## **Macroeconomics and Monopoly Capitalism**

*Ben Fine and Andy Murfin*

This book is a critique of current economic theory—Monetarism, Keynesianism and post-Keynesianism. The authors describe the economic characteristics of modern capitalism, emphasizing the role of giant corporations and governments, examine Keynesianism and Monetarism both in terms of their internal logic and their relevance to the past and future growth of the capitalist economy, and explore the strengths and weaknesses of the radical tradition associated with Baran, Sweezy, Kalecki and the post-Keynesians, discussing issues of monopolization and crisis. **"This book is a well-written critical appraisal. . . . Economists working within those traditions [discussed] should feel obligated to respond to the important arguments developed in this book."**—*Malcolm C. Sawyer,*

*University of York*

1984

170 pp.

ISBN 0-312-50336-9

\$22.50

## Markets, Entrepreneurs and Liberty

An Austrian View of Capitalism

W. Duncan Reekie

This book is a comprehensive survey of the main tenets and methodological approach of Austrian economics, exploring the uniqueness of Austrianism in economic thought and its relevance to economics as a whole in the late twentieth century. The author traces the evolution and growth of Austrian economics, and discusses such topics as the role of exchange, entrepreneurship and the theory of trade cycle, which offers one of the few satisfactory explanations of the high level of unemployment in today's economy.

1985

171 pp.

ISBN 0-312-51533-2

\$27.50

## Public Enterprise Economics

Second Edition

Ray Rees

This book is a fully updated and comprehensive analysis of the pricing, output and investment problems of public enterprises. Particular emphasis is placed on the actual dilemmas these institutions currently face and on the principles which would allow them to be run in a decentralized way. Topics discussed include the purposes and performance of public enterprises, welfare economics, marginal-cost pricing, taxation and income distribution. Appendices provide explanations of mathematical derivations used in the text.

1984

238 pp.

ISBN 0-312-65439-1

\$27.50

## Demand, Equilibrium and Trade

Essays in the Honor of Ivor F. Pearce

edited by A. Ingham and A. M. Ulph

This volume contains thirteen essays by leading economists that analyze Pearce's work on the theories of demand, general equilibrium, trade and capital, and economics as a whole; and offer critical reassessments and new findings in such areas as the Keynes-Ramsey Rule, Le Chatelier Principle, measures of complementarity and transfer pricing.

1984

256 pp.

ISBN 0-312-19187-1

\$37.50

## Expectations

Theory and Evidence

K. Holden, D. A. Peel and J. L. Thompson

This book is a synthesis of recent research and thought on the subject of expectations. The authors provide introductions to the use survey measures of expectations, the adaptive expectations approach, the concept of rational expectations, and the use of time series modelling. With this foundation, they discuss such topics as the implications of expectations in single-equation studies, the efficient markets hypothesis, the role of expectations in the consumption function and wage equation, the representation of expectations in both large- and small-scale macroeconomic models, the formation of aggregate expectations, and the combination and impact of forecasts on asset markets.

ISBN 0-312-27599-4

\$25.00

## New in Paperback!

### Rational Expectations

An Elementary Exposition

G. K. Shaw

A basic introduction to the subject, written at a non-technical level. Shaw examines the need for expectations theory, and the static, adaptive and Keynesian treatment of expectations. He then considers rational expectations as a reaction to earlier work, its policy implications and its relation to Monetarism, business cycle theory and supply side economics. **"I am impressed by this as an introductory book for students. Professor Shaw succeeds in explaining rational expectations in a way that will be readily understood by undergraduate students."**—Professor J. Black, University of Exeter **"This is the only beginner's-level book on this subject of which this reviewer is aware."**—Choice

1984

131 pp.

The American Economics Association (AEA) is now soliciting applications to host the AEA Summer Program for Minority Students, for three summers beginning in 1986.

This program is now in its twelfth year and is currently at the University of Wisconsin at Madison. Previous host institutions have been Berkeley, Northwestern, and Yale.

The intent of the program is to increase the number of Blacks, Hispanics, and Native Americans pursuing the Ph.D. in Economics. In recent years the course of study has been an intensive eight to ten week program in intermediate microeconomics and macroeconomics, at the honor's level, and courses in econometrics or mathematical economics.

Funding for the program has been provided by the hosting institutions and grants to the AEA. Applications should be sent to Professor Donald J. Brown, chairman of the AEA Committee on the Status of Minority Groups in the Economics Profession, CSMGEP, no later than September 1, 1985.

## THIRD WORLD DEFAULT!

Two new books on the international debt situation focus on the dangers of default to the global economy.

**The Costs of Default**, by Anatole Kaletsky of London's *Financial Times*, argues that the debt burden on Third World countries has so limited their economic growth that political pressures for some form of default are building up. He suggests there may be a series of "conciliatory" defaults and calls for new negotiations leading to cooperation between debtor and creditor nations.

**The Debt of Nations**, by M. S. Mendelsohn, a financial writer who is a consultant to the World Bank and the Group of Thirty, argues that all involved have a stake in an orderly resolution of the crisis. He predicts that the debtor countries will manage to avert default.

These books cost \$7.00 each, plus \$1.00 postage and handling.

Please send prepaid orders to:

The Twentieth Century Fund • 41 East 70th Street • New York, NY 10021

New from the IMF . . .

### **Foreign Private Investment in Developing Countries**

#### ***A Study by the Research Department***

Since the early 1970s, foreign private investment in developing countries has been dwarfed as a source of capital by debt-creating bank credit. This shift may have rendered recipients more vulnerable to external difficulties; meanwhile, it is predicted that bank lending to these countries will grow relatively slowly over the medium term. Both these factors imply that foreign private investment could become more important.

Number 33 in the Occasional Paper Series of the International Monetary Fund, this paper examines the reasons for the decline of foreign direct and portfolio equity investment, its role in development and external adjustment, and, in this context, the policies of both recipient and source countries that might encourage larger flows.

Price: US\$7.50 (US\$4.50 to university libraries, faculty members, and students)

# SUPPLEMENT YOUR MICRO, TRADE, AND PUBLIC FINANCE COURSES WITH GEMODEL

## A GENERAL EQUILIBRIUM MODEL

for the IBM PC, Apple II+ and TRS-80

GEMODEL is easy-to-use, menu-driven micro-computer software that solves real general equilibrium models in their non-linear form and:

- runs either as a 3-factor, 3-industry model or as a 2-factor, 2-industry model, with several consumer classes in both cases.
- solves within seconds closed and open economy models with or without international capital flows.
- illustrates at the touch of a key almost any aspect of Price, Trade, Taxation & Distribution theories. It is an indispensable tool for analysis of second-best problems. It will enrich your courses with discussion of numerical results.

GEMODEL uses nested CES utility and production functions to simulate the effects of changes in:

- factor endowments
- tariffs
- technology and productivity
- terms of trade
- tastes for goods and leisure
- interindustry relations
- and taxes.

GEMODEL simulates the allocative and distributive effects of a large array of taxes:

- corporate income tax
- social security and payroll taxes
- retail sales taxes
- progressive personal income tax
- property taxes
- taxes on sales of intermediate inputs
- and import duties;

as well as a similar array of subsidies and lump-sum redistributions of tax revenue.

GEMODEL will save your data and reload them for new simulation runs. Default values are provided for use without data input.

# Economic Growth in the Third World, 1850-1980

Lloyd G. Reynolds

This book is the first to draw together into a systematic framework the increasing body of literature on the economic histories of individual third world countries. Focusing on the forty-one largest countries in Asia, Africa, and Latin America, Reynolds shows that the third world has a rich historical record of growth and that its growth patterns bear some resemblance to those observed earlier in Europe and North America. A Publication of the Economic Growth Center \$35.00

# What Is Political Economy?

*A Study of Social Theory and Underdevelopment*  
Martin Staniland

In "the most comprehensive and sensible guide to the political economy literature available" (William J. Foltz), Staniland explores current meanings of the term political economy, particularly as it is applied to situations in the third world. He critically analyzes a broad variety of theories, including rational choice theory, dependency theory, politicism, interdependence theory, and neo-Marxism. \$18.50

# Yale

Yale University Press  
Dept. 781J 92A Yale Station New Haven, CT 06520

# Policy, Power, and Order

*The Persistence of Economic Problems in Capitalist States*  
Kerry Schott

Inflation, unemployment, and slow growth have been persistent problems in all Western economies and neither Keynesian nor neoclassical policies seem able to remedy this. In this lucid book, Schott argues that the assumptions on which economic policy is based are naive and inconsistent. Criticizing both Marxist and individualist analyses of the role of the state, she stresses the fundamental importance for economists of political and social conditions and changing power relationships, and uses this to examine both the different investment and growth performances of various nations in recent years and the dilemmas now confronting economic policy makers. \$20.00

# Wayward Capitalists

*Target of the Securities and Exchange Commission*  
Susan P. Shapiro

This pathbreaking study describes the types, strategies, and impact of securities fraud and documents how these crimes are detected and handled by the SEC. Based on an inside look at SEC records over a twenty-five-year period, the book concludes with policy recommendations to improve the agency's work as the government's watchdog over the stock market. \$26.00

# Defending White-Collar Crime

*A Portrait of Attorneys at Work*  
Kenneth Mann

The first detailed description of what lawyers specializing in white-collar crime defense work do to prevent their clients from being indicted or convicted, this book raises important ethical questions about the nature of the legal profession in the United States. \$25.00

# United Nations Periodicals

## CTC REPORTER (CENTRE ON TRANSNATIONAL CORPORATIONS)

Reports on matters related to transnational corporations in all governmental and non-governmental organizations. Issued three times per year, including special supplement, in English, French and Spanish.

*Annual rate \$20.00*

*Single issues \$9.00*

## MONTHLY BULLETIN OF STATISTICS

Provides monthly statistics on seventy-four subjects from over two hundred countries and territories, including special tables that graphically portray important economic developments. Quarterly data for significant world and regional aggregates are also reflected in the Bulletin. Issued monthly in a bilingual English/French edition.

*Annual rate \$150.00*

*Single issues \$16.00*

## Computer Access to Articles in the JEL Subject Index

On-line computer access to the *JEL* and *Index of Economic Articles* data base of journal articles is currently available through DIALOG Information Retrieval Service. DIALOG file 139 (*Economic Literature Index*) contains complete bibliographic citations to articles from some 260 journals listed in the quarterly *JEL* issues from 1969 through the current issue. The abstracts in *JEL* since June 1984 are also available as part of the full bibliographic record. The file may be searched using free-text searching techniques or author, journal, title, geographic area, date, and other descriptors, including descriptor codes based on the *Index's* four-digit subject classification numbers.

## MONITORING GROWTH CYCLES IN MARKET-ORIENTED COUNTRIES

**Philip A. Klein and Geoffrey H. Moore**

*A National Bureau of Economic Research book*

Shows how the system of indicators developed over the past fifty years can be successfully applied to growth cycles, as well as to classical business cycles; shows further how this system can be applied to growth cycles in other countries with case studies of: Canada, the United Kingdom, the Federal Republic of Germany, France, Italy, Sweden, Belgium, the Netherlands, and Japan.

May 1985 — 288 pages

## THE LEVEL AND COMPOSITION OF HOUSEHOLD SAVING

**Patric H. Hendershott, Editor**

*Sponsored by the American Council of Life Insurance*

Analyzes the quantity and form of household saving, including wealth and portfolio changes of households, and specific economic decisions: purchases of consumer durable goods, the demand for pension savings, and investment in human capital such as education. Addresses the importance of corporate and government saving in the determination of household saving.

1985 — 328 pages

## AMERICAN JOBS AND THE CHANGING INDUSTRIAL BASE

**Eileen L. Collins and Lucretia Dewey Tanner, Editors**

Addresses the American worker's plight in the face of technological change. Details new patterns of trade, productivity, and industrial realignment in an effort to assess the future structure of U.S. employment.

1984 — 258 pages

## EXCHANGE RATES, TRADE, AND THE U.S. ECONOMY

**Sven W. Arndt, Richard J. Sweeney, and Thomas D. Willett, Editors**

*An American Enterprise Institute book*

Analyzes the data now available on the transition of the world's economy from fixed to floating exchange rates, considers the effects of flexible rates on international trade, and covers the macroeconomic linkages and influence of international affairs on the U.S. macro economy.

1985 — 328 pages

## REVITALIZING AMERICAN INDUSTRY

**Milton Hochmuth and William Davidson, Editors**

Argues for a national industrial policy to replace *ad hoc* and fragmented measures that can't protect us from tough newly industrialized competitors like Korea, Taiwan, Brazil, and Mexico.

1985 — 420 pages

## FREE WHEN YOU ORDER 3 TEN YEARS OF MULTINATIONAL BUSINESS

**Malcolm Crawford and James Poole, Editors**

*An Abt Book/ECONOMIST INTELLIGENCE UNIT special series*

Case studies of India, off-shore tax planning, currency swaps, SKF, Brown Boveri, McKinsey, DuPont, and major oil companies are included.

1982 — 184 pages

## MATHEMATICAL AND STATISTICAL PROGRAMMING PACKAGE FOR YOUR IBM PC

FAST • EASY TO USE • POWERFUL

# GAUSS™

YOU'VE NEVER SEEN ANYTHING LIKE IT!

**GAUSS** is a sophisticated mathematical and statistical programming package for the IBM PC and compatibles. It combines **speed, power, and ease of use** in one amazing program.

**GAUSS** allows you to do essentially anything you can do with a mainframe statistical package — and a lot more.

Personal computers are friendly, convenient, and inexpensive. So is **GAUSS**. **GAUSS** is not just a stripped-down mainframe program. **GAUSS** has been designed from the ground up to take advantage of all of the conveniences of a personal computer. After trying **GAUSS**, you may never use a mainframe again.

**GAUSS** comes with programs written in its matrix programming language that allow you to do most econometric procedures, including OLS, 2SLS, 3SLS, PROBIT, LOGIT, MAXIMUM LIKELIHOOD, and NON-LINEAR LEAST SQUARES.

In the current version, **GAUSS** will accept up to 90 variables in a regression. There is no limit on the number of observations.

**GAUSS** will do a regression with 10 independent variables and 800 observations in under 4 seconds — and with 50 variables and 10,000 observations in under 18 minutes. It will compute the maximum likelihood estimates of a binary logit model, with 10 variables and 1,000 observations, in 1-2 minutes, depending upon the number of iterations required.

**GAUSS** allows you to do complicated statistical procedures that you would never imagine trying on a mainframe. It is easy to program almost any routine, and **GAUSS** is so fast that it can do almost any job. But the nicest thing of all is that the cost of time on your personal computer is essentially zero!

**GAUSS** is an excellent teaching tool. It makes programming easy and allows students to focus on concepts and techniques.

If you can write it mathematically, you can write it in **GAUSS**. Furthermore, you can write it in **GAUSS** almost exactly the way you would write it mathematically.

**GAUSS** is 10-15 times faster than other programs that use the 8087, and 15-100 times faster than other programs that do not use the 8087.

As in APL, single statements in **GAUSS** can accomplish what might take dozens of lines in another language. However, **GAUSS** provides you with additional powerful numerical operators and functions — especially for statistics and the solution of linear equations — that are not found in APL. And, of course, the syntax in **GAUSS** is much more natural (for most of us) than that in APL.

**GAUSS** has state-of-the-art numerical routines and random number generators.

**GAUSS** is extremely accurate. It allows you to do an entire regression in 19 digit accuracy. It will compute the Longley benchmark coefficients in 5 hundredths of a second with an average of 11 correct digits! (Try that on a mainframe!)

**GAUSS**, with its built-in random number generators and powerful functions and operators, is an excellent tool for doing simulations.

## GAUSS and the 8087 NUMERIC DATA PROCESSOR GIVE YOU MINICOMPUTER PERFORMANCE ON YOUR DESKTOP.

### SPECIAL INTRODUCTORY OFFER

With 30 Day Money

Back Guarantee ..... Reg. 395.00 **\$250.00**

**GAUSS** requires an IBM PC with at least 256K RAM, an 8087 NDP, 1 DS/DD disk drive, DOS 2.0 (or above).

ORGANIZATION FOR ECONOMIC COOPERATION AND DEVELOPMENT

## **International Banks and Financial Markets in Developing Countries**

*Dimitri Germidis and Charles-Albert Michalet*

Examines whether international banks which establish themselves in developing countries contribute to the development of the host countries, and how they effect local banking systems. Also examines the impact of international offshore financial centers on development.

41 84 04 1

94 pages

ISBN 92-64-12635-X

\$13.00

## **Investing in Free Export Processing Zones**

*Antoine Basil and Dimitri Germidis*

Analyzes the role of free export processing zones in attracting export-oriented foreign investment, assesses their impact on the host country's economy, and explores the problem of the relations between foreign firms operating in the free zone and domestic industries.

41 84 05 1

68 pages

ISBN 92-64-12634-1

\$11.00

## **Main Economic Indicators: Historical Statistics 1964-1983**

The new edition of this information-packed volume presents 20-year series of data for such economic variables as GNP; production, deliveries, and stocks by industry; rate of capacity utilization; housing starts; retail and wholesale sales; employment and unemployment; producer and consumer prices; imports and exports, and much more. Data is provided for every OECD country. The base year used on indicators is 1980, and data is shown on a monthly, quarterly, and annual basis.

31 84 21 3

656 pages

ISBN 92-64-02606-9

\$35.00

## **National Accounts, 1984 Edition Volume II: Detailed Tables 1970-1982**

This newly revised and expanded annual includes tables for each OECD country showing main aggregates, private final consumption expenditure by type and purpose, gross fixed capital formation by kind of activity of owner, gross accounts for central government, accounts for state or provincial government, accounts for local government, accounts for social security funds, accounts for financial and non-financial corporate and quasi-corporate enterprises, accounts for households and private unincorporated enterprises, external transactions/current and capital accumulation accounts, capital finance accounts by sector, gross domestic product by kind of activity, cost components of value added, and profit shares and rates of return on capital. Values are expressed in national currencies.

# INDEX OF ECONOMIC ARTICLES

prepared under the auspices of  
*The Journal of Economic Literature*  
of the  
*American Economic Association*

- ✓ Each volume in the **Index** lists articles in major economic journals and in collective volumes published during a specific year.
- ✓ Most of the **Index's** volumes also include articles of testimony from selected congressional hearings in government documents published during the year.
- ✓ No other single reference source covers as many articles classified in economic categories as the **Index**.
- ✓ The 1977 volume contains over 10,500 entries.

## Currently available are:

## EVSEY D. DOMAR

DISTINGUISHED FELLOW

1984

In a celebrated series of papers, beginning in 1946 and extending over a decade, Evsey Domar became one of the founding fathers of the modern study of economic growth. He and Roy Harrod—whose point of view was rather different, although the adjective “Harrod-Domar” entered our lexicon for good—revived for our time the grand long-term dynamical questions that preoccupied the great economists of the eighteenth and nineteenth centuries. What is more, they insisted that the investment requirements of long-term growth were an essential backdrop to and causal factor in shorter-run economic fluctuations.

Evsey Domar’s second career was in the study of comparative economic systems, as befits a scholar who arrived on the East Coast of the United States by way of Manchuria. As a student of the economy of the USSR as an analyst of the cooperative firm, and as the propounder of an extraordinarily fruitful historical generalization about the origin of slave and serf systems, his example has taught a generation of economists the value of a broad historical, geographical, and institutional imagination.

## Editor's Note

Manuscripts submitted for publication in the *American Economic Review* after March 1, 1985, will be handled by a new procedure. Each paper will be assigned to one of three Co-Editors, or retained by the Managing Editor, for supervision through the review process *and* for a final decision on the manuscript status. Robert Haveman, University of Wisconsin-Madison, John Riley, University of California-Los Angeles, and John Taylor, Stanford University, have agreed to join me as Co-Editors in this new endeavor.

It is my hope that our new editorial procedure will allow due recognition in the editorial process for the wide variety in both the substantive and methodological character of manuscripts submitted to the *Review*. It should also be possible to obtain these benefits without a significant increase in the length of time required to review and process submitted manuscripts.

I am especially pleased to report that Wilma St. John, Production Editor of the *Review* for seventeen years, has agreed to continue in that capacity at the new editorial office of the *Review* at 169 Nassau Street, Princeton, NJ 08542-7067.

# What Will Take the Con Out of Econometrics?

By MICHAEL MCALEER, ADRIAN R. PAGAN, AND PAUL A. VOLKER\*

More than twenty years ago Carl Christ recounted a story about a new typist who rendered "econometrics" as "economic tricks." No doubt this tale was greeted with some amusement at that time; equally without doubt, today it would probably only occasion wry and knowing smiles. Charting the course of this transition, and accounting for its direction, has been the concern of a number of recent articles. Perhaps the most perceptive of these has been Edward Leamer's article (1983). His contribution is of special interest, as it seeks not only to be descriptive but prescriptive; methods are outlined, the use of which Leamer sees as essential to the restoration of confidence in econometric research. Such techniques have now been promulgated and applied in a number of contexts. Thomas Cooley (1982), for example, looks at the impact of industry concentration upon profits; Louis Dicks-Mireaux and Mervyn King (1984) consider the effect of pensions on savings; Cooley and Stephen LeRoy (1981) are concerned with money demand. These constitute just three of the more prominent applications.

Although the number of applications of the methods is growing, and approving references are being made to them, surprisingly few have queried the basis of the contention that the procedures really do allay some of the suspicion greeting econometric results; a singular exception being Phoebus Dhrymes

(1982). Yet the claims being made for this methodology are such as to demand a close investigation. As witnesses to these claims we quote Leamer and Herman Leonard:

We propose that researchers be given the task of identifying interesting families of alternative models and be expected to summarize the range of inferences which are implied by each of the families. When a range of inferences is small enough to be useful and when the corresponding family of models is broad enough to be believable, we may conclude that these data yield useful information. When the range of inferences is too wide to be useful, and when the corresponding family of models is so narrow that it cannot credibly be reduced, then we must conclude that inferences from these data are too fragile to be useful. ...

...The proper test of our proposals is whether they are useful in practice. We believe that researchers will find them to be efficient tools for discovering the information in data sets and for communicating findings to the consuming public. [1983, p. 306]

The aim of our paper is to consider possible answers to the question in the title. Because of its position as one proposed answer, and its strong advocacy by a number of authors (for example, Cooley and LeRoy, p. 827), we pay particular attention to Leamer's *Extreme Bounds Analysis (EBA)*. In our inquiry, contained in Sections I, II, and III, the discussion is structured along the lines of the three themes in the statement above: the effect of looking at different families of models, the determinants of a fragile inference, and the nature of the conclusions that may be drawn from the information provided by *EBA*. Based on the arguments of those sec-

\*McAleer and Pagan: Department of Statistics, The Faculties, Australian National University, Canberra, A.C.T. 2600, Australia; Volker: Bureau of Labour Market Research, Canberra. An earlier version of this paper appeared as a Working Paper in Economics and Econometrics, No. 097, Australian National University. It is available on request. We thank all those who commented on that version. We believe that those comments sharpened our arguments considerably. Special thanks go to Ed Leamer, Tom Cooley, Trevor Breusch, David Hendry, Allan Gregory, Hashem Pesaran, Peter Schmidt, and Pravin Trivedi.

tions, we conclude that *EBA* does not go very far in removing the con from econometrics. Furthermore, in most instances, it can actively distract a researcher from asking important questions about an econometric model.

But just because the promise and the performance of *EBA* diverge, it does not obviate the need for a methodology aiming to dispel doubts arising over conventional research presentation and analysis. Accordingly, Section IV sets out our own prescription, the basic ingredients of which are the necessity for a clear and full disclosure of the process whereby a preferred model was selected, and the requirement that a thorough evaluation has been made of the properties of such a specification. Such an orientation is scarcely original, reflecting in its concerns an oral tradition that owes much to Denis Sargan's (1964) influential paper on wages and prices. Nevertheless, it is worth explicitly stating these principles, as our experience convinces us that, consistently applied, they can go a long way towards the "de-conning" of econometrics. As an example of this approach, and to contrast our prescription with *EBA*, Section IV below re-examines the conclusions drawn by Cooley and LeRoy from their demand for money study.

### I. The Problems in Families

Trying to define "the family" nowadays is enough to give a sociologist a nervous breakdown. To keep things simple one is inclined to assign a few individuals to its core and then to generate a whole range of alternatives by adding on children, grandparents, aunts, uncles, and other "relatives." Such a homely analogy captures rather nicely the essence of the "family of models" mentioned by Leamer and Leonard. At their core are variables classified as *important*. Added on are variables termed *doubtful*. What demarcates them is that *only the latter can be combined in an arbitrary linear fashion*. We emphasize this definition, since much of the discussion and use of *EBA* tends to proceed as if the division were based upon whether the associated coefficients are likely to be

zero or not.<sup>1</sup> Because this is not so, the decision to assign variables to their respective classifications is not a trivial one, and we explore it in detail in Section III.

To complete the elements of *EBA*, the concept of a *focus* variable is needed. This derives from the assumption that the magnitude of one of the model coefficients is of special interest. By itself, this feature tells us nothing about the nature of such a variable; it may be free or doubtful. Examples of both are given by Leamer (1983). His "bleeding heart liberal" regards the impact of execution probability upon murders as doubtful, while his "right winger" treats the same variable as free.

Proponents of *EBA* work with the maximum and minimum point estimates of the focus coefficient as the set of restrictions upon the doubtful variables is changed. If the gap between these values is wide, readers are generally informed that no reliable inference can be drawn about the influence of the focus variable. Thus Cooley and Le Roy express the belief that almost nothing can be said about the value of the interest elasticity of the demand for money. Within one of their families of models this elasticity could lie anywhere between  $-6.27$  to  $2.24$ .

Now it is a rare family that does not have a member with problems at some stage or other. Families of models also share this characteristic, but this is rarely mentioned by *EBA* advocates. Notwithstanding that, it has to be the case that a consumer of the conclusion drawn from an application of the methodology must take some notice of the nature of the model that generated the extreme bounds. When this is done, there are at least two situations in which inferences drawn from *EBA* would have to be heavily discounted.

<sup>1</sup>Unfortunately, the terminology of "important" and "doubtful" tends to bolster this impression. For this reason, we substituted "free" for important as that captures the nature of these variables much more closely. Ideally, a similar change would have been desirable for doubtful.

First of all, the restrictions that are being imposed upon the doubtful variables may be entirely unacceptable. Suppose that  $\gamma_1$  and  $\gamma_2$  are the parameters associated with the income and lagged dependent variable terms in a money demand function, and both variables are treated as doubtful. Then a restriction of the form  $\gamma_2 - \theta\gamma_1 = 0$ , with  $\theta$  negative, would offend against theoretical conceptions. An extreme bound generated with  $\theta < 0$  in a money demand example would be of little interest and, yet, there is nothing to safeguard against such a possibility. While Leamer himself is aware of this problem (see Leamer, 1978, p. 199), there have been few attempts at cautioning users of *EBA* about it. Cooley and LeRoy do not mention it at all, despite the fact that income and wealth elasticities associated with one of the extreme bounds of the ninety-day Treasury bill rate are actually negative.

Attempts have been made to limit such conflicts. Leamer (1982) restricts the feasible parameter space by requiring an investigator to put upper and lower limits on prior variances. It is hard to know what to make of this "solution," as the choice of such limits is extremely difficult and essentially arbitrary. One person's view of what constitutes a reasonable bound is unlikely to coincide with another's, and there is always the residual suspicion that prior variances have been chosen to yield narrow or tight bounds. As a satisfactory alternative to current practice it leaves much to be desired. It re-introduces the very element of whimsy that *EBA* was supposed to ameliorate.

A second alternative is to ensure that the extreme bounds do not disagree too greatly with the sample. Cooley does this by invoking the constraint that estimates should lie within the  $\alpha$  percent confidence ellipsoid associated with the least squares estimates of the complete model. A range of sample-modified bounds can then be generated by varying  $\alpha$ . When  $\alpha = 100$ , the ordinary extreme bounds are found.

Once we introduce the sample evidence to constrain the alternative models, we are implicitly being asked to accept a number of conventions underlying *EBA* (at least as pre-

sented in the literature). Namely, that the errors in models be normally distributed, nonautocorrelated, and homoscedastic; that the regressors be predetermined; and finally, that sample sizes are large enough for "confidence intervals" to be known with accuracy. No doubt these conventions may be appealing, but Leamer himself has pointed out the problem with their use: "Though the use of conventions does control the whimsy, it can do so at the cost of relevance" (1983, p. 38). That principle is certainly applicable here, as the breakdown of any of these conventions means that the " $\alpha$  percent confidence intervals" are anything but, and exactly what constraint is being applied becomes increasingly hazy.

These considerations emphasize the absolute necessity to know the point estimates of all coefficients in the model generating the bounds. But such knowledge is still not sufficient to decide if we have just come across a problem child or not. It is perfectly possible for all point estimates to appear reasonable, but for the model to be rejected on other grounds, such as when it exhibits substantial serial correlation. An extreme value generated from such a model would not be of great interest, since an investigator would not regard it as a suitable candidate for conveying information about the focus coefficient. Without knowing the *full set of characteristics* of the models generating the extremes, it is impossible to know what weight should be placed on the latter. Mere provision of the bounds, as in Cooley and LeRoy for example, is not enough. Much more information is needed to assess whether these bounds are meaningful.

## II. When is an Inference Fragile?

In what has transpired so far we have been somewhat vague about exactly how the bounds are used to conclude that an inference is fragile. If left that way, *EBA* becomes a "black box," and no understanding of the factors leading to an inference being fragile would be available. For this reason, we have gleaned two interpretations of fragility from the literature applying *EBA*, each of

which is sufficiently precise to enable analytical results to be established.

The first of these, henceforth referred to as Type *A* fragility, is given by Leamer and Leonard as follows:

These extreme values,  $\hat{\beta}_{\min}$  and  $\hat{\beta}_{\max}$ , delineate the ambiguity in the inferences about  $\beta$  induced by the ambiguity in choice of model. If the interval  $[\hat{\beta}_{\min}, \hat{\beta}_{\max}]$  is short in comparison to the sampling uncertainty, the ambiguity in the model may be considered irrelevant since all models lead to essentially the same inferences. [p. 307]

With the sampling uncertainty measured as  $k$  times the estimated standard deviation of the focus coefficient,  $k$  being a predetermined constant, such a definition has been adopted by Leamer-Leonard, Cooley, and Cooley-LeRoy. The first provide no guidance about  $k$ , Cooley selects a value of  $k=4$ , while the last opt for  $k=2$ . To investigate the consequences of adopting this definition of fragility, we provide Proposition 1 (proof available on request).

#### PROPOSITION 1:

(a) *When the focus variable is doubtful, the necessary and sufficient condition for Type A fragility to exist is that the chi-square statistic for the doubtful variable coefficients to equal their prior means ( $\chi_D^2$ ) exceeds  $k^2$ .*

(b) *When the focus variable is free, the necessary condition for Type A fragility is that  $\chi_D^2 > k^2$ .*

Proposition 1 is quite striking, as it shows that whether an inference is to be Type *A*-fragile or not depends upon two quantities: namely, the significance of the doubtful variables in the model and the value chosen for  $k$ . Regarding the first, its magnitude will depend crucially upon the prior means assumed for the doubtful variables. If the prior means are taken to be zero, whereas the *OLS* estimates lie a long way from that point, a large value of  $\chi_D^2$  is likely. The closer the means are to the *OLS* values, the smaller will be  $\chi_D^2$ , and the less the evidence of

fragility. Everything therefore depends upon the whimsy of the reporter in the choice of prior means for doubtful variables! Hardly a good method for getting rid of the con artists. Instead it gives them enormous scope for generating almost any result they like. In the examples of *EBA* usage available, only D. G. Fiebig (1981) attempts to spell out this sensitivity of bounds to prior mean specification.

Proposition 1 moreover tells us something else of importance: that inferences will only be fragile if doubtful variables are informative. Assuming for convenience that prior means are zero, a large value of  $\chi_D^2$  signals to a researcher that these variables should appear in any model from which inferences are to be drawn. From this perspective, *EBA* is just an inefficient (and incomplete) way of communicating to readers the fact that the doubtful variables are needed to explain the data; a better solution would be to just present estimates of the general model along with an associated  $\chi_D^2$  statistic, letting consumers of research judge whether any further simplification of the model is justified.<sup>2</sup>

The analytic results presented in Proposition 1 can also rationalize the findings of a number of different investigations in which *EBA* has been employed. Leamer and Leonard's nuclear reactor example treats as doubtful those variables with *t*-values all below 1.03, leading to a lack of Type *A* fragility. In contrast, Cooley's profits regressions exhibit four variables with *t*-statistics greater than 3.5, and three of the four *always* appear as doubtful variables. Is it any wonder then that he concludes that Type *A* fragility exists for a concentration/profits relationship?

Perhaps the ambiguities raised above could be dissipated by an alternative definition of

<sup>2</sup>It is of interest to specialize  $k$  to 2. When only a single doubtful variable is present Type *A* fragility occurs when the *t*-statistic of the doubtful variable exceeds 2, which is a conventional rule of thumb for selection of regressors. As the number of doubtful variables grows, however, a constant value of  $k=2$  means that the comparison of  $\chi^2$  with 4 corresponds to larger and larger levels of significance. Most researchers would presumably find this implicit assumption in *EBA* a little odd.

fragility. Leamer and Leonard provide just that, and we will designate it as Type *B* fragility in what follows. They say: "An alternative definition of shortness derives from a decision problem based on  $\hat{\beta}$ : the interval is short if all values in the interval lead to essentially the same decision" (p. 307, fn. 1).

When implemented by Leamer (1983), Type *B* fragility occurs if there is a sign change implicit in the bounds. Ignoring, as Leamer does, the fact that these bounds themselves have standard errors, we proceed to analyze the nature of this type of fragility using Proposition 2 (proof available on request).

#### PROPOSITION 2:

(a) *When the focus variable is doubtful the necessary and sufficient condition for Type B fragility to exist is that  $\chi_D^2 > \chi_{F0}^2$ , where  $\chi_{F0}^2$  is the  $\chi^2$  statistic for testing if the focus coefficient is zero.*

(b) *When the focus variable is free, the necessary condition for Type B fragility is  $\chi_D^2 > \chi_{F0}^2$ .*

The movement from Type *A* to Type *B* fragility only changes the benchmark against which the significance of the doubtful variables is checked. It is no longer set by the reporter but determined by the data ( $\chi_{F0}^2$ ). Furthermore, when the focus variable is doubtful, it is always the case that  $\chi_D^2$  exceeds  $\chi_{F0}^2$  (ignoring singularities in the design matrix), and so Type *B* fragility is in evidence. While such a result is solely a consequence of the fact that zero is an admissible value for that doubtful variable coefficient, it serves to emphasize how Type *B* fragility may evenuate purely by a classification of variables. An example of this is provided by Leamer in his discussion of the impact of execution on murders. After placing the execution variable in the doubtful class, thereby producing an opposite sign to that from unrestricted least squares, he concludes: "I come away...with the feeling that any inference from these data about the deterrent effect of capital punishment is too fragile to be believed" (1983, p. 42).

Since the sign change did not depend in any way upon the data, we find such a conclusion a trifle hard to defend.<sup>3</sup>

#### III. When is a Variable Doubtful?

Propositions 1 and 2 strongly suggest that the conclusions on fragility drawn from *EBA* are intimately bound up with the classification of variables as doubtful and free. The polar case where the focus variable is orthogonal to all other regressors gives a striking demonstration of that fact. When treated as free, the gap between the bounds is zero, as the point estimate of the focus coefficient is entirely insensitive to combinations of other variables. But, when treated as doubtful, the width of the bounds varies directly with  $\chi_D^2$ ; the more significant the focus variable the greater the degree of fragility inferred.

A concrete example may serve to highlight just how important this choice can be to the outcome. Accordingly we consider the model of murder rates set out in the April 1983 SEARCH manual (it resembles that in Leamer, 1982). Table 1 gives the extreme bounds, range (the absolute value of the difference between the bounds), and ratio of range to standard errors for the impact of execution on murders under different variable designations.

As the definition of Type *A* fragility reflected the relative magnitudes of the range and standard deviation, the last column of Table 1 contains the information that would be used to assess whether inferences about the impact of executions upon murders are fragile. Clearly the decision about which variables are doubtful can have enormous consequences for any conclusions. Such variation naturally poses the question of how we are to know which one of the four options is

<sup>3</sup>Note that a sign change also occurred when the execution variable was free under the "eye-for-eye" specification. With eleven doubtful variables, and a *t*-statistic of less than two for the execution coefficient, an application of Proposition 2(b) should leave us in little doubt over why that was so.

TABLE 1—EXTREME BOUND INFORMATION FOR EXECUTION COEFFICIENT (*PX*)

Free Variables	Min	Max	Range	Range/ <i>SD</i>
None	-2.87	2.72	5.59	115.0
<i>PX</i>	-.45	1.35	1.8	37.0
<i>PX</i> , intercept	-.40	.10	.5	10.3
<i>PX</i> , intercept, other variables with $t > 3(S, PC,$ <i>PCTPOOR</i> )	-.22	-.01	.21	4.3

Note: *PC* = probability of conviction, *PX* = probability of execution, *S* = sentence, *PCTPOOR* = percent poor, standard deviation of focus coefficient = .0486, *SD* = standard deviation.

to be adopted? Or, when is a doubtful variable doubtful? The answer must be that there is no answer. A decision to nominate a variable as doubtful is a personalized one, resting very much upon the opinions and values of the nominator. Consensus is no more likely over this choice than in the traditional selection of regressors problem.

Having elicited this point, the most serious defect in *EBA* becomes transparent: unless extreme bounds are presented for *all* possible classifications of variables as doubtful and free, an observer cannot be certain that the selection does not constitute a "con job." *Selectivity in regression reporting therefore has as an exact analog in EBA the different classifications of variables as doubtful and free.* *EBA* users report results for only particular variable categories and so are as arbitrary and selective in their modus operandi as the practices they criticize and claim to be improving on.

We can see this effect in Table 1. With nine variables in the regression there are 181,440 possible doubtful/free splits. Hence, inevitably some selection from this huge number will be made. Someone intent on demonstrating that executions deter murders would undoubtedly quote the final classification (or an augmented version), while those wishing to denigrate such a position would opt for the first two doubtful variable choices. There seems no reason to suppose that all of the classifications in Table 1 would be given by either protagonist, any more than one would anticipate each individual presenting the equivalent set of regressions composed of the different types of free variables. Thus

there is little reason to believe that *EBA* provides a reporting style that is any better than that currently practiced.

Sections I–III can now be drawn together to highlight the fact that *EBA* is not a satisfactory solution to the question posed in the title of this paper.<sup>4</sup> Section I argued that the extreme bounds themselves are not enough to enable conclusions to be drawn regarding fragility; we need to know the characteristics of the models generating such bounds. Sections II and III demonstrated that *EBA* is as capable of manipulation as the traditional presentation it aims to replace; perhaps more so in one respect in that an additional arbitrary choice of prior mean must be made. Consequently, if one feels unhappy with the information provided by *selective regressions*, one should not be any more satisfied with extreme bounds obtained by *selective variable partitions*. A con man in one mode would have no fear of becoming deskilled in the other.

#### IV. Cooley and LeRoy's Demand for Money Function: Contrasting the Methodologies

Given our belief that *EBA* cannot de-con econometrics, is there anything that might?

<sup>4</sup>It is important to emphasize that an answer to this question is our central concern. We do not quibble with the contention that *EBA* displays the impact of prior information on posterior means. To do so would be inconsistent with our Proposition 1. Nor do we argue that, for a given variable partition, *EBA* might not be useful. In Section IV we do, in fact, exploit it in exactly such a context.

Not generally, as there are almost certainly instances in econometrics, just as in science, of outright fraud. Nothing will detect such deception, except a vigorous critical tradition and a requirement that utilized data be either available or easily replicable. But our perception of the skepticism greeting many econometric studies is that it does not arise from a high incidence of such a phenomenon. Rather it stems from a feeling that the sins are venial rather than mortal; something has been left undone that should have been done.

Now *EBA* clearly addressed itself to this problem by indicating, for a given variable partition and universe of variables, the worst outcomes if everything conceivable were done. What it leaves undetermined is both the process by which the partition it is conditional upon was arrived at, and the operating characteristics of models generating the extremes. Three points therefore always need to be considered in assessing an *EBA*. In turn, these three elements also occur in the traditional line of research and are, we believe, the source of much of the dissatisfaction with it. Because they are pivotal to the methodology advanced in this section, we list them below:

- A. Selection of a general model;
- B. How and why any general model was simplified to the preferred one(s);
- C. Quality control of the preferred model(s).

Selection of a general model is a problem with all research methodologies (including *EBA*) and we can do no better than concur with Leamer and Leonard when they say: "But it is up to readers of research to decide if the reported family of models is credibly inclusive. If the researcher, for whatever reason, selects an incredibly narrow family of models, readers will properly ignore the results" (p. 307).

Even if we largely agree that the choice of variables considered in an investigation was commendably large, it is frequently the case that little discussion is provided of the strategy employed to obtain a more parsimonious representation of the data. Where a systematic reduction is possible, it should be followed; where it is not, detail should be

sufficient to enable a consumer of the research to determine exactly the criterion adopted in performing the simplification. At a very minimum this forces the presentation of an estimated general model and some analysis of how the preferred model relates to it.

Our final category focuses upon the quality control exercised on the models presented. Frequently, this is little short of abysmal and, as James Ramsey comments, "...it is amazing that so little is done to evaluate the model and the results" (1983, p. 242). Yet, ultimately, quality control is as important for the econometrics profession as it is for automobile manufacturers. A gradual realization of this point has in fact stimulated the development of criteria for the formal evaluation of models. For later reference it is useful to summarize the outcome of that research by classifying derived methods into five major categories:

- 1) Consistency with theory; 2) Significance, both statistical and economic; 3) Indexes of inadequacy; 4) Fragility or sensitivity; 5) Whether a model can encompass or reconcile previous research.

These five categories can be viewed as a regrouping of the criteria suggested in David Hendry and Jean-François Richard (1982) for settling upon a "tentatively adequate" model. Categories 1 and 2 have tended to dominate in past evaluative analysis and even now constitute the corpus of most applied econometrics courses and texts. Increasing attention has, however, been paid to the necessity of item 3, with Hendry (1980) giving a general perspective and Hendry (1983) a detailed application. Robert Engle (1982b) and Pagan and Anthony Hall (1983) provide an account of much of the technology, emphasizing that these methods aim to extend the horizon in directions where errors might be anticipated. Some indexes, such as the Durbin-Watson statistic, have been routinely used in applied work. But, as the articles referenced above demonstrate, the set of indexes *conventionally* reported is much too small to be completely effective.

Item 4 encompasses considerations raised by *EBA*. However, in contrast to the emphasis placed by *EBA* upon sensitivity of point

estimates to a change in the menu of included variables, there is an older tradition of assessing the fragility of models by reference to new data. This is done either through predictive failure, recursive estimation, or interaction with other parts of a model as in simulation analysis. Fragility as an important criterion for model evaluation is therefore not a novel idea. Rather it is the emphasis *EBA* places upon variation in point estimates of a particular coefficient under model respecification which is novel. In fact, an *EBA* would seem to constitute an important part of the evaluative process. It must be a rare instance in which some arbitrariness does not creep into the simplification process, particularly when working with cross-section data. The extreme bounds then provide useful information upon the effects of such arbitrary decisions, at least in respect of the focus coefficient. Such is the way we employ *EBA* in the following case study.

The final category distinguished above challenges a model to encompass or explain alternative models, particularly those originating from past endeavours. Lack of reconciliation between studies is a glaring defect in much current applied research, and this requirement, whether interpreted formally as in Grayham Mizon and Richard (1982), or rather more informally as in James Davidson et al. (1978), must become an essential cornerstone for applied econometric research. Only if it is met can one be truly satisfied that progress has been made in understanding an empirical phenomenon.

In order to contrast the methodology outlined above with the approach of those viewing *EBA* as the cornerstone of econometric work, we will look at the money demand function inquiry presented in Cooley and LeRoy. This paper has been cited approvingly by a number of authors, both for what it said about econometric practice and for its claim about the likely magnitudes of interest elasticities. In doing our comparison we have presumed that the study was meant to be a serious application of the *EBA* methodology, rather than just illustrative. Certainly, there is support for this hypothesis in the stress Cooley and LeRoy laid upon the conclusions drawn from their analysis.

TABLE 2—EXTREME BOUNDS FOR LONG-TERM INTEREST ELASTICITY (*RTB*)

Free Variables	Min	Max
None	-12.14	12.15
<i>RTB</i>	-6.27	2.24
<i>RTB</i> , intercept	-.375	.019

One fact that should by now be apparent from our assignation of *EBA* to a group of methods for model evaluation, is our belief that exclusive attention to the results from it can lead to quite erroneous conclusions about the robustness of parametric inferences. Such tunnel vision tends to distract researchers from the other vital questions needing to be asked. A primary example would be whether the model upon which *EBA* is being practiced is comprehensive enough. Later it is argued that, in Cooley and LeRoy's case, there is ample evidence of it not being so.

For the moment we accept their formulation of the problem, turning instead to one of the items in the list assembled earlier as bedeviling *EBA*; namely, the way in which conclusions on fragility are attendant upon the assumed doubtful/free division. Our Table 2 shows how important such selections were for Cooley and LeRoy's conclusions concerning their second specification (see their Table 2, p. 836).

The extreme bounds shrink dramatically when the intercept is made a free variable. (Note that Cooley and LeRoy, Table 1, p. 835, do not indicate it as doubtful but the bounds of -6.27 and 2.24 from their Table 2 only occur when it is so treated.) With a *t*-statistic of -3.96, such an outcome should not be surprising given our Proposition 1 above. Building a case for the treatment of the intercept as doubtful rather than free would, to our minds, be quite difficult, but the most important lesson from Table 2 is how misleading it is to give the extreme bounds for a single doubtful/free partition of the variables.<sup>5</sup>

<sup>5</sup>In fact, Cooley and LeRoy present a broader range of bounds than those in Table 2, invoking the extra constraint that coefficient estimates must lie in a specified

TABLE 3—ALTERNATIVE ESTIMATES OF THE MONEY DEMAND FUNCTION<sup>a</sup>

<sup>a</sup>All regressors except the inflation rate are in logs. Constant term is not shown. Standard errors are shown in parentheses, *SEE* = standard deviation of residuals, *D-W* = Durbin-Watson statistic.

<sup>b</sup>For the preferred regression this column is  $\Delta \ln W$ .

<sup>c</sup>Coefficient of lagged real money (in logs).

Table 2 shows that any of the conclusions drawn by Cooley and LeRoy about the magnitude of interest elasticities must be treated with skepticism, even if the output of *EBA* is taken as the dominant source of information on these parameters. The wide bounds relied upon for their critique appear to have been manufactured solely by a particular variable classification. But the inadequacies in their work are even more serious than that. No attention was paid by them at all to the quality of the model used for *EBA*, and it is therefore appropriate that we briefly review it.

In Cooley and LeRoy's specification the demand for real money (*M1*) is held to be a function of two interest rate variables, the savings and loan passbook rate (*RSL*) and the ninety-day Treasury bill rate (*RTB*), real *GNP* (nominal *GNP* divided by the *GNP* deflator, *P*), the current inflation rate (*INF*), the real value of credit card transactions (*VCC*), and real wealth (*W*). They use seasonally adjusted quarterly data for the period 1952:II to 1978:IV, and present (p. 834)

estimates for a loglinear specification. Our estimates of their model are shown in Table 3.<sup>6</sup>

To evaluate Cooley and LeRoy's estimated equation, it is sufficient to note that the most basic index of inadequacy, the Durbin-Watson statistic, is 0.063. This is an example of the situation condemned by C. W. J. Granger and P. Newbold (1974) in which the Durbin-Watson statistic is markedly exceeded by the  $R^2$  and in which arises the danger of the "spurious regression" phenomenon. It is clearly not sensible to investigate fragility with such an inadequate model.

From the above discussion one is entitled to be dubious of the validity of Cooley and LeRoy's claim that the interest elasticity of the demand for money cannot be known with much precision. Nevertheless, it could be correct. Moreover, in view of the prominence of the topic in the literature, and the particular stand taken by Cooley and LeRoy on the issue, it is interesting to see what type

confidence ellipsoid. Those in Table 2 correspond to the 100 percent ellipsoid, and represent wider bounds than most contained in their Table 2.

<sup>6</sup>Cooley kindly made their data available to us. We were able to reproduce their results with the exception that the real wealth elasticity should be  $-0.107$  rather than  $+0.107$ , and the inflation rate should not be in logarithms since negative rates were observed over the sample period.

of model would have eventuated, *given only the data series used by Cooley and LeRoy as input*, if a proper modeling strategy had been followed.<sup>7</sup> That strategy involves the three stages described at the beginning of this section.

#### A. Selection of the General Model

Under the restriction on the universe of available variables, the main direction in which generalization of Cooley and LeRoy's model can take place is in the order of dynamics. Given the wide use of distributed lags in modeling money demand, it seems extraordinary that the authors chose to ignore Christopher Sims' maxim that "a time series regression model arising in econometric research ought in nearly every case to be regarded as a distributed lag model until proven otherwise" (1974, p. 289). The omission of dynamics is even stranger in the light of Cooley and LeRoy's own comments: "Such lagged endogenous variables as the lagged money stock... cannot plausibly be excluded from the demand side either explicitly as observable explanatory variables for the demand for money or implicitly through the time dependence of the error" (p. 840).

Our general model therefore has the same variables as Cooley and LeRoy, but with four lags on all variables (including the dependent). This lag structure seems reasonable considering the data used are quarterly. The period selected for study was, however, shorter than that used by Cooley and LeRoy. John Judd and John Scadding (1982) have recently noted that a large number of studies have experienced difficulty in estimating conventional money demand functions for the post-1973 period. Not only do these models predict poorly, but in a large number of cases such models are dynamically unstable. Various reasons for the poor performances of the models are canvased by Judd and Scadding. Among them, "the most likely

cause of the observed instability in the demand for money after 1973 is innovation in financial arrangements" (p. 1014), which originated from the rapid rise in inflation during the period. In accordance with this view, we restricted ourselves to the subsample 1952:II to 1973:IV, with the first four observations used for constructing up to four lags on all variables.<sup>8</sup>

#### B. Simplification of the General Model

Our first step in simplification of the general model represents an attempt to determine the order of dynamics on each of the variables through a sequence of nested tests. The procedure we use was proposed by Sargan (1980), and has been termed the COMFAC algorithm, due to the fact that it seeks to determine common factors in the distributed lag polynomials associated with each variable. Briefly the logic of the method is as follows.

Suppose the general model had the form

$$(1) \quad y_t = b_1 y_{t-1} + \dots + b_4 y_{t-4} + c_0 x_t + \dots + c_4 x_{t-4} + e_t.$$

With the aid of lag operators, (1) can be rewritten as

$$(2) \quad b(L)y_t = c(L)x_t + e_t,$$

where  $b(L) = 1 - b_1 L - \dots - b_4 L^4$  and  $c(L) = c_0 + c_1 L + \dots + c_4 L^4$  are polynomials in the lag operator  $L$ . If the term  $(1 - \rho_1 L)$  is a common root of both polynomials, (2) can be reexpressed as

$$(3) \quad b^*(L)y_t = c^*(L)x_t + u_t,$$

$$\text{with} \quad b(L) = (1 - \rho_1 L)b^*(L),$$

$$c(L) = (1 - \rho_1 L)c^*(L),$$

$$\text{and} \quad (1 - \rho_1 L)u_t = e_t.$$

<sup>7</sup>The restriction seems necessary to avoid the situation where differences in any conclusions we reach to those of Cooley and LeRoy are simply a consequence of our using information not available to them.

<sup>8</sup>The counterpart to Cooley and LeRoy's model over this shorter period gives parameter estimates  $-2.90$ ,  $-.021$ ,  $-.382$ ,  $-.009$ ,  $-.616$ ,  $-.017$ , and  $-.052$  with standard error of estimate .0083.

TABLE 4—TESTS OF COMMON FACTORS (83 OBSERVATIONS)

Common Factor	Unrestricted Lag Length	Restricted Lag Length	F-Statistic	D.F.	Critical F(0.01)
1,2	4	2	1.755	(12,48)	2.59
3,4	2	0	3.904	(12,60)	2.50
3	2	1	0.426	(6,60)	3.12

An examination of (3) shows that the presence of a common factor has created a new model with maximum lag of three in  $y_t$  and  $x_t$ , and first-order serial correlation ( $AR(1)$ ) in the errors. As there were nine parameters in (2) and only eight in (3), a restriction has been imposed, whose validity may be tested. If the restriction is accepted, the model is capable of being simplified. Moreover, if  $\rho_1$  turns out to be zero, the original model must have had both the orders in  $y_t$  and  $x_t$  overstated.

In our general model there are six regressors apart from the intercept. Hence, in the analogous move from (2) to (3), six restrictions are being imposed in the first attempt at simplification. If the first common factor is accepted, imposing the second leads to a further six restrictions, with the equation error now given as  $AR(2)$ ,  $u_t = \rho_1 u_{t-1} + \rho_2 u_{t-2} + e_t$ . In this way, each additional common factor restriction leads to six fewer estimated coefficients. Since we have a sequence of nested tests, we set the level of significance of each test at 1 percent so as to have an overall level of significance of approximately 4 percent.<sup>9</sup>

There are two difficulties that can arise in using the  $F$ -test to test the common factors. First, there will generally be multiple minima for the sums of squares (see Sargan, 1980) and, second, there is no guarantee that the common roots in the polynomials attached to the variables are real. In order to guard

against complex roots, we test for two common factors initially, and then test for one common factor only if two are rejected. Thus, in testing for the first two common factors in Table 4, the calculated  $F$ -statistic is 1.7555, the unrestricted (restricted) lag length is 4 (2) and 12 restrictions are being tested (6 associated with each common factor).

Compared with the critical value of  $F(12, 48, .01) = 2.59$ , the calculated statistic is not significant. At this stage, then, the lag length has been reduced from 4 to 2 and the equation error can be expressed as  $AR(2)$ . Testing third and fourth common factors gives a value of 3.904 for the  $F$ -statistic which is significant at 1 percent. Therefore, the third and fourth common factors are rejected. Returning to the second-order lag and testing for the third common factor only gives a value of 0.426 for the  $F$ -statistic. Since the calculated value is significantly less than 3.12, three common factors are accepted. The model can now be expressed as one lag on all variables, with an equation error given as  $AR(3)$ . The resulting model is referred to as the "simplified" one in Table 3.

The following observations are relevant to the simplified dynamic specification given in Table 3. Of the four interest rates, only current  $RSL$  is significant, and, apart from the lagged dependent variable, the only significant lagged variable is real wealth. Moreover, current and lagged wealth have coefficients which add to zero exactly. Neither the current nor lagged real value of credit card transactions exerts a significant effect on real balances. Finally, the third common factor ( $\rho_3$ ) is not significantly different from zero, thereby reducing the implicit lag length of the specification by one.

It is fairly clear that the model is still overparameterized. Accordingly, we imposed a further eight restrictions, namely zero

<sup>9</sup>To test the restrictions, we used the standard  $F$ -test given by  $F = [(\bar{e}'\bar{e} - \hat{e}'\hat{e})/\hat{e}'\hat{e}] \cdot [(T - \hat{k})/r]$ , where  $\bar{e}'\bar{e}$  is the sum of squared residuals from the restricted model,  $\hat{e}'\hat{e}$  is its unrestricted counterpart,  $(T - \hat{k})$  is the degrees of freedom of the unrestricted model, and  $r$  is the number of restrictions to be tested. In this way some allowance is made for the number of parameters estimated in the unrestricted model.

TABLE 5—INDEXES OF ADEQUACY FOR THE PREFERRED MODEL

Statistic Type		Statistic Value		Critical Value	
RESET <sup>a</sup>		3.27		$F(2, 74, .01) = 4.9$	
Diff. Test <sup>b</sup>		2.59		$\chi^2(8, .01) = 20.09$	
Normality Test <sup>c</sup>		1.74		$\chi^2(2, .01) = 9.21$	
Hetero. Test <sup>d</sup>		1.82		$\chi^2(1, .01) = 6.63$	
A.C.F. of squared residuals <sup>e</sup>		1) -.68    3) .51		S.N.D. (.01) = 2.33	
		2) .49    4) .36			
A.C.F. of residuals <sup>f</sup>		1) 1.22    3) 0.73    5) 1.62    7) 0.22			
		2) 1.17    4) 0.53    6) 0.28    8) 1.12			

<sup>a</sup>The  $F$ -test that the coefficients of the predictions squared and cubed in the regression of the residuals against these and the derivatives are zero. Computation was done via partitioned inversion to avoid serious numerical inaccuracy.

<sup>b</sup>The differencing test of Charles Plosser et al. (1982). One iteration of Sargan's (1959)  $AIV$  estimator upon the differenced model was performed from the estimates in Table 3. Instruments for the derivatives with respect to the coefficients of  $M_{t-1}$  and  $u_{t-1}$  were constructed as in Plosser et al. (fn. 7).

<sup>c</sup>The joint normality test of K. O. Bowman and L. R. Shenton (1975), or Anil Bera and Carlos Jarque (1981).

<sup>d</sup>The  $LM$  test that  $\gamma = 0$  in  $\sigma^2 = \sigma^2(E(y_t))^\gamma$  where  $y_t$  is the dependent variable of a regression. Pagan et al. (1981) derive this  $LM$  test but it was proposed originally as a test for heteroscedasticity by F. J. Anscombe (1961).

<sup>e</sup>The  $t$ -statistics were formed by regressing the squared residuals against their lagged values. This approach was used by Granger and Allan Andersen (1978) for the detection of nonlinear models but can also be used to check for Engle's (1982a)  $ARCH$  effects or as a general specification error test.

<sup>f</sup>Writing the model as a nonlinear regression  $y = f(X; \theta) + \varepsilon$ , the  $t$ -statistics that the coefficient of the lagged residuals  $\hat{\varepsilon}_{t-j}$  are zero in the regressions of  $\hat{\varepsilon}_t$  against  $\hat{\varepsilon}_{t-j}$  and  $\partial f_t / \partial \theta$  for  $j = 1, \dots, 8$ .

coefficients for  $VCC$  and the lagged values of  $RTB$ ,  $RSL$ ,  $INF$ ,  $GNP$ , and  $VCC$ , a zero sum for the wealth coefficients, and a zero value for the third common factor. The calculated  $F$ -statistic of 1.001 is significantly less than  $F(8, 66, 0.01) = 2.8$ , leading to acceptance of the restrictions. Our preferred model is therefore the last one listed in Table 3.

### C. Quality Control: Is the Model a Lemon?

How does the estimated model in Table 3 stand up to the five criteria for quality control listed at the beginning of this section? With the exception of the term  $\Delta \ln W_t$ , it constitutes a very traditional specification of money demand. The presence of the change in, rather than the level of, wealth is however consistent with theoretical considerations. If transactions requirements are held constant, that is,  $GNP_t$  is fixed, the fact that money ( $M1$ ) is an asset dominated for portfolio purposes by interest-bearing deposits of near equal liquidity suggests that the long-term

wealth effect should be zero. In the short run though, it has been frequently noted that changes in wealth are initially held as demand deposits before reallocation, and the combination of  $\Delta \ln W_t$  and the lagged dependent variable describes such a process, the implied lag distribution being .178, -.029, -.025, etc. Perhaps the only difficulty with such an interpretation is that the portfolio reallocation process is not faster.

Table 5 investigates whether there are any obvious "inferential monsters lurking beyond the horizon," by augmenting the moments of the preferred model with a number of variables designed to capture inadequacy. No striking deficiencies are in evidence. A number of other experiments were conducted to determine whether it was possible to reject the chosen model by the addition of particular variables. These included a number of lags in real  $GDP$ ,  $RSL$ , etc., time trend, seasonal dummies, and estimation with up to seventh-order serial correlation pattern. None of these augmentations was found to contribute anything of significance. A final point

worth mentioning is that *t*-statistics, made robust to heteroscedasticity as suggested by Halbert White (1980), were about 10 percent higher than those in Table 3. The only exception to this rule—that for inflation—was only slightly smaller.

A check on parameter constancy is available by examining the size of prediction errors made when an equation is estimated over a particular sample and then used to forecast out of sample.<sup>10</sup> In this vein, the preferred model was estimated to 1970:IV and one-step prediction errors were generated from 1971:I to 1973:IV by augmenting the preferred equation with the Type *B* constructed variables in Pagan and Desmond Nicholls (1984). The "*F*-test" that the coefficients on the twelve constructed variables were jointly zero was 1.58, well below the critical *F*(12, 62, .01) value of 2.49. Although an examination of the individual errors does reveal one large error, namely that for 1972:I, where the *t*-value was 2.58, the prediction errors for 1971–73 were much the same as the sample errors, with an average absolute value of .4 percent.<sup>11</sup>

#### D. Are Interest Elasticities of Money Demand Zero?

As our model was of satisfactory quality to 1973:IV, it is reasonable to utilize it to shed light on the question of whether data is uninformative about interest elasticities, as alleged by Cooley and LeRoy.<sup>12</sup> Conditional

upon the structure of the final model being valid, we can say that all variables in the estimated relationship (including *both* interest rates) are highly significant, and to adopt their hypothesis of a zero interest rate effect as an acceptable interpretation of the data would be totally inappropriate. To be sure, this final specification was arrived at after a decision in which an arbitrary group of variables was dropped because of insignificance. To assure readers that the well-defined interest elasticities found in our preferred model were not dependent upon this action, and to illustrate what we believe is the place of *EBA*, we computed the extreme bounds for the two long-run interest elasticities. This was done by making the coefficients on either *RSL* or *RTB* the focus, treating all excluded variables as doubtful, and using the estimates of parameters on  $\ln M_{t-1}$ ,  $\ln RTB_t$  (or  $\ln RSL_t$ ),  $\ln RTB_{t-1}$  (or  $\ln RSL_{t-1}$ ) associated with the bounds to obtain long-run responses. To be consistent with Cooley and LeRoy, we concentrate upon the long-run elasticities as they summed lagged coefficients when dynamics were admitted. These bounds were extremely narrow, being  $-.053$  to  $-.068$  (*RTB*) and  $-.400$  to  $-.441$  (*RSL*), indicating that the effect of interest rates upon money demand was not sensitive to our decision to exclude certain variables.

#### V. Conclusions

That applied econometrics is not currently in the most robust of health is hard to deny, and it would be difficult to find as entertaining or as perceptive an analysis of its ills as that found in Leamer's various articles. What concerns us is that the prescriptions made in those articles are inappropriate, in part because of faulty diagnosis. Extreme bounds analysis (*EBA*) is most emphatically *not* the medicine to cure an ailing patient.

Section I argued that extreme bounds are generated by the imposition of highly arbitrary

<sup>10</sup>A more detailed analysis is available in our earlier working paper.

<sup>11</sup>Although our model gave satisfactory performance up to 1973, just like automobiles, age finally caught up with it, and after that date its predictive performance declined dramatically. For the twelve quarters after 1973:IV, the *F*-test that prediction errors were zero was 5.69, with only the errors for 1974 not being significantly different from zero individually. The absolute error was 1.7 percent over this three-year period. Thus Stephen Goldfeld's (1976) puzzle of the "missing money" is certainly not resolved by working with Cooley and LeRoy's data alone.

<sup>12</sup>Encompassing tests were also advocated to assess model quality. These are not really possible here given the restriction placed upon the data set, although it is clear that our model dominates those which exclude either *RSL* or *RTB*, the inflation rate, wealth or

explicit dynamics. In Hendry and Richard's terminology, our model strongly variance-encompasses Cooley and LeRoy's as is apparent from the standard errors of estimate in our fn. 8 and Table 3.

trary, and generally unknown, restrictions between the parameters of a model. Exactly why such bounds should be of interest therefore becomes something of a mystery. Furthermore, as shown in Sections II and III, the methodology is flawed on other grounds. *EBA* demands a general, adequate model from which the bounds may be derived, and a consensus over which variables are critical to a relationship. These are highly questionable conventions and we demonstrated, both theoretically and empirically, that deviations from them almost completely negate the utility of *EBA*.

After largely rejecting *EBA*, Section IV of the paper moved on to our own diagnosis and prescription. Both are founded on the belief that many of the difficulties applied econometrics currently faces originate in the very poor attempts currently made to accurately describe the process whereby a model was selected, and to ascertain its adequacy. Acceptance of this proposition leads to the necessity for the establishment and promulgation of standards with which to conduct applied research. Many other disciplines have faced and taken steps to solve this problem, and movement in this direction is long overdue in econometrics. With these considerations in mind we proposed a three-stage approach to modeling, involving the selection and subsequent simplification of a general model and a rigorous evaluation of any preferred model. Under the latter heading, five ways of performing such an evaluation were distinguished. It may not be too fanciful to think of such criteria as a "checklist" to be applied when reviewing or performing applied work. Only if a model passes most items on the list should it be seriously considered as augmenting our knowledge.

Having set up some yardsticks with which to evaluate models, Section IV applied them to the money demand example in Cooley and LeRoy. Their specification was found to fail even the simplest of these criteria, making any conclusions drawn from it highly suspect. In sharp contrast to this failure, the application of a modeling strategy beginning with a general model and progressively constraining the parameter space led to a representation which passed all items of the

checklist. This example highlighted the benefit of a systematic approach to modeling and model evaluation.

In closing, a confession. We are only too aware that what has been described are the necessary rather than sufficient conditions for taking the con out of econometrics. As any users of corporate accounts will be aware, there are many ways around standards. But that is not to deny their value. It serves only to highlight the need.

# Sensitivity Analyses Would Help

By EDWARD E. LEAMER\*

A fragile inference is not worth taking seriously.

All scientific disciplines routinely subject their inferences to studies of fragility. Why should economics be different? It hasn't been different up to now. Nor do I think it ever will be, notwithstanding the comments of Michael McAleer, Adrian Pagan, and Paul Volker (1985).

Decentralized studies of fragility are common whenever an inference matters enough to attract careful scrutiny. When Isaac Erlich (1975) claims to have demonstrated that capital punishment deters murders, he elicits a great outpouring of papers that show how the result depends on which variables are included (B. Forst 1977), which observations are included (A. Blumstein et al., 1978), how simultaneity problems are dealt with (P. Passell, 1975), etcetera, etcetera. These disorganized studies of fragility are inefficient, haphazard, and confusing.

What we need instead are organized sensitivity analyses. We must insist that all empirical studies offer convincing evidence of inferential sturdiness. We need to be shown that minor changes in the list of variables do not alter fundamentally the conclusions, nor does a slight reweighting of observations, nor correction for dependence among observations, etcetera, etcetera.

I have proposed a form of organized sensitivity analysis that I call "global sensitivity analysis" in which a neighborhood of alternative assumptions is selected and the corresponding interval of inferences is identified. Conclusions are judged to be sturdy only if the neighborhood of assumptions is wide enough to be credible and the corresponding interval of inferences is narrow

enough to be useful. But when an incredibly narrow set of assumptions is required to produce a usefully narrow set of conclusions, inferences from the given data set are reported to be too fragile to be believed.

In dramatic conflict with real data analyses, theoretical econometricians behave as if a given data set admitted a unique inference. This priesthood takes as their self-appointed task the uncovering of the elaborate method by which the unique inference can be squeezed from a data set. Indeed, this is the reaction of McAleer et al., who offer a method of squeezing Thomas Cooley and Stephen Leroy's (1981) data set. They propose to deal with specification ambiguity by charting one *ad hoc* route through the thicket of possible models. Complicated *ad hoc* searches like the one they suggest have no support in statistical decision theory, and virtually none in classical sampling theory. What is to be made of a procedure that sets scores of parameters to zero if they are not "statistically significant" at arbitrarily chosen levels of significance? And what inferences are allowable after a model passes a battery of "specification error" tests that are sometimes more numerous than even the set of observations? This recommendation of McAleer et al. merits the retort: "There are two things you are better off not seeing in the making: sausages and econometric estimates," to which they might reply: "It must be right, I've been doing it since my youth."

## I. Extreme Bounds Analysis

McAleer et al. direct their criticisms at what they call "extreme bounds analysis."<sup>1</sup>

<sup>1</sup>I prefer to use the words "extreme bounds" to refer to the largest possible set of inferences that a given data set will admit. This largest possible set of inferences depends on the largest possible family of models cum priors that the researcher is willing to entertain. The family of models that give rise to what McAleer et al.

\*Department of Economics, University of California, Los Angeles, CA 90024. Helpful comments from Sebastian Edwards, John Riley, and especially Harold Demsetz are gratefully acknowledged.

Since most of their concerns stem from misunderstandings about the setting in which this applies, I will begin my reply with a careful description of the specification ambiguity that properly gives rise to this form of sensitivity analysis. This setting is most accurately described in Bayesian terms, but to communicate with non-Bayesian readers I often adopt the more familiar language of the specification searcher. I fear it is the translation that causes the problems.

In Bayesian terms, the "extreme bounds" are applicable when the prior distribution for a subset of coefficients is located at the origin but is otherwise unspecified, and the prior distribution for the other coefficients is "diffuse." A sensitivity analysis is then performed to determine if features of the posterior distribution depend importantly on the way this partially defined prior distribution is fully specified. It is particularly easy to search over the set of alternative posterior distributions to find the extreme posterior modes of linear combinations of coefficients, ergo "extreme bounds."

It has been my experience that this Bayesian description of the "extreme bounds analysis" meets with equally small amounts of approval and understanding. To combat this ignorance and suspicion, I have tried to market the idea in the following disguise. Imagine the estimation of a regression in a setting in which there are a few variables that are always left in the equation (the free variables), and some others that the researcher feels comfortable experimenting with (the doubtful variables).<sup>2</sup> Normally, this experi-

mentation is limited to a small subset of the possible models that could have been estimated. Suppose instead that we consider the whole continuum of models in which the free variables and any one linear combination of the doubtful variables are included in the model. If it turns out that inferences about issues of interest are essentially the same for all choices of the linear combination of doubtful variables, then there need be no debate about which doubtful variables ought to be deleted. If, as is often the case, this bound turns out to be uselessly wide, then either the inferences are reported to be too fragile to be useful, or the bounds are narrowed in one way or another.

This disguised treatment of the sensitivity issues is quite alright up to this point, but an explicitly Bayesian framework is required to discuss sensibly any attempt to narrow the bounds. Unfortunately, the transition to the proper Bayesian foundation of the analysis is not easy for many people. For example, McAleer et al., and others as well, remark that the extreme estimates come from a model that includes a very strange linear combination of the doubtful variables. To cure this "problem," it is often proposed to restrict the bounds to the set of regressions that exclude subsets of the doubtful variables, a procedure that can be called "all subsets regression." But this advice depends on the parameterization of the model, which is usually chosen by whim rather than design. In a distributed lag model, the "all subsets regressions" would be different if  $x(t)$  and  $x(t-1)$  are doubtful variables than if  $x(t)$  and  $x(t) - x(t-1)$  are doubtful variables, since in the former case the omission of  $x(t)$  leaves  $x(t-1)$  as the included variable, whereas in the latter case  $x(t) - x(t-1)$  is retained.<sup>3</sup>

How should the parameters be defined? The subject of sensitivity analysis provides an answer. Regression coefficients should be defined about which prior opinions are inde-

call "extreme bounds analysis" may or may not be the widest set under consideration. In order to bring attention to this difference in language, I will put quotation marks around the words when used in the sense of McAleer et al.

<sup>2</sup>A terminological error that was first made in my earlier study (1978, p. 194) and adopted vigorously by myself and H. B. Leonard (1983) is the use of "focus" rather than "free" to describe the variables that are always in the equation. It is often but not always the case that the free variables are also the focus variables. An earlier version of the paper by McAleer et al. had comments that rested on this terminological error, and at my suggestion they have adopted the word free.

<sup>3</sup>As a matter of fact, unless you are prepared to commit to a particular coordinate system, the restriction to all subsets regression is vacuous since all subsets in all coordinate systems will reproduce exactly the extreme bounds.

pendent. If, before the data are observed, opinions about  $b(1)$  do not depend on information about  $b(2)$ , then these are suitable choices for the pair of coefficients but  $b(1)$  and  $b(1) + b(2)$  are not. The reason for defining the model with a priori independent coefficients is that, if the prior distribution cannot be more fully specified, the "all subsets" bound applies (see my article with Gary Chamberlain, 1976) and is generally narrower than the "extreme bounds." For the distributed lag example, the model should be written as  $y = b(1) \times (x(t) + x(t-1)) + b(2) \times (x(t) - x(t-1))$  if the best guess of  $b(1)$ , the steady-state responsiveness of the dependent variable, is unaffected by information about  $b(2)$ , the responsiveness to changes in the level of the stimulus. In that event, if both variables are regarded to be doubtful, it makes sense to see what happens to the estimate of  $b(1)$  when  $b(2)$  is set to zero, and it makes sense to see what happens to the estimate of  $b(2)$  when  $b(1)$  is set to zero.

Classical inference offers no advice on how to choose a parameterization. It is altogether immaterial whether  $x(t)$  and  $x(t-1)$  are the explanatory variables, or  $x(t)$  and  $x(t) - x(t-1)$ , or  $(x(t) + x(t-1))$  and  $(x(t) - x(t-1))$ . As a result, there is total confusion in the literature about anything that depends on the coordinate system, the multicollinearity problem being the prime example.<sup>4</sup>

"All subsets" regression replaces the extreme bounds if the prior distribution is suitably restricted. There are many other bounds that could be computed depending on how fully the prior distribution is specified. The restricted family of prior distributions that I often find appealing has a fixed prior mean

and an "interval" of prior covariance matrices (see my 1982 article). The "extreme bounds analysis" is one special case with an unbounded interval of covariance matrices for a subset of coefficients and a sharply defined covariance matrix for the others. This somewhat unusual interval of prior distributions is often and properly criticized for being too wide on one subset and too narrow on the other. Indeed that is the criticism of McAleer et al., though of course they don't use this language to express their concerns.

McAleer et al. offer some useful caveats about "extreme bounds analysis," pointing out the important point that the bounds depend on the family of prior distributions. I am confident that on reflection the properties that seem to bother them will be judged to be altogether desirable, and I welcome the glare of publicity that they offer. These properties are:

1) The bounds depend on the choice of variables that are treated as doubtful.

2) If coefficients are set to values other than zero, different bounds will result. (This amounts to saying that the bounds depend on the location of the prior distributions.)

3) The bounds for the free coefficients will be wider the more statistically significant are the doubtful variables.

4) If a variable is treated as doubtful, a zero estimate for its coefficient is necessarily obtainable.

5) If there are two or more doubtful variables, a coefficient on a doubtful variable may be either positive or negative, regardless of the degree of correlation between the variables.

If you do find these properties undesirable, it must be that you are implicitly rejecting the family of prior distributions on which they are based. It is no surprise that "extreme bounds analysis" does not apply in all cases. As a matter of fact, it rarely applies. I use it primarily as a warm-up device for introducing the kind of bounds that I think are truly applicable. I welcome this kind of criticism of the "extreme bounds analysis" since it affords me the opportunity to enrich the vocabulary of the conversation by demonstrating the proper Bayesian foundation of the analysis. With this enriched vocabulary it

<sup>4</sup>After all, there is always a coordinate system in which the "variables" are orthogonal and in which by traditional standards there is no multicollinearity problem. I have repeatedly but unsuccessfully tried to explain this simple point. Expressed most dramatically, since orthogonality is a happenstance of the coordinate system, there may still be a multicollinearity problem if the explanatory variables are orthogonal, though it is more accurate to say that there is a problem of dimensionality. For more, see my earlier articles (1973 or 1978, or 1983).

is possible to demonstrate how other, more relevant bounds may be computed.

## II. Global Sensitivity Analysis

The real point of disagreement between myself and other econometricians is that I believe the only "model selection" game in town ought to be the global sensitivity game. Except for issues associated with data-instigated models and simplification problems, both of which are dealt with in my earlier study (1978), a sensible and general characterization of the problem of inference begins with a broad family of alternative models and a representative, but hypothetical, prior distribution over that family. Because no prior distribution can be taken to be an exact representation of opinion, a global sensitivity analysis is carried out to determine which inferences are fragile and which are sturdy. A neighborhood of prior distributions around the representative distribution is selected and inferences that depend in a significant way on the choice of prior from this neighborhood are judged to be fragile. Ideally, the neighborhood of distributions is credibly wide, and the corresponding interval of inferences is usefully narrow. But if it is discovered that an incredibly narrow neighborhood of prior distributions is required to produce a usefully narrow set of inferences, then inferences from the given data set are suspended, and pronounced too fragile to serve as a basis for action.

I don't pretend that this research strategy is easy. It certainly is not a comfortable one for those trained in and wedded to classical inference. It isn't something that can be done by a computer without the aid of a human. I recognize that it will take some considerable experience with these methods until we can decide what constitutes a "credibly" wide set of assumptions. One thing that is clear is that the dimension of the parameter space should be very large by traditional standards. Large numbers of variables should be included, as should different functional forms, different distributions, different serial correlation assumptions, different measurement error processes, etcetera, etcetera.

In principle, a global sensitivity study should be carried out with respect to all dimensions of the model in one grand exercise. Alas, the mathematical/computational problems in dealing with the list of etceteras are very severe. But since the longest journey begins with a single step, a piecemeal approach is proposed in which the sensitivity analysis is carried out with respect to a limited number of dimensions of the model. The parameters that lend themselves to the most congenial analysis are regression coefficients, but I can give you some interesting and useful results on errors in variables (Steven Klepper and myself, 1984), and on the distribution of residuals (my 1981, 1983a, 1984 articles, and C. Z. Gilstein and myself, 1983a; b).

When you review a global sensitivity analysis, you need ask yourself two important questions: is the dimension of the model space adequate? Is the neighborhood of prior distributions the right width—wide enough to include all sensible distributions but not so wide that it includes nonsensical ones? I interpret the comments on Cooley and Leroy by McAleer et al. to amount to a healthy discussion of exactly these two issues. This I believe is precisely the form that debates about empirical results ought to take. McAleer et al. find Cooley and Leroy's space of models inadequate because it includes no parameters for the dynamics, and they find the neighborhood of priors to be both too wide (allowing funny linear restrictions) and too narrow (some of the free variables might be doubtful). The very fact that they are able to make these comments reveals the value of the global sensitivity framework for focusing the issues.

McAleer et al.'s "most serious" charge is:

Unless extreme bounds are presented for *all* possible classifications of variables as doubtful and free, an observer cannot be certain that the selection does not constitute a "con job." *Selectivity in regression reporting therefore has as an exact analog in EBA the different classifications of variables as doubtful and free.* [p. 298]

This charge seems to be based on the belief that the distinction between free and doubtful variables is altogether arbitrary. Actually the split should be selected to represent as accurately as possible the other relevant information that is required to draw sensible inferences from the given data set. When readers differ concerning their willingness to believe and/or to use other relevant information, then a menu of inferences should be presented, and as clear as possible a statement should be made about the assumptions that are necessary to make one inference or another. When the menu isn't broad enough to suit your tastes, there is no reason to believe the inferences claimed by the author. For example, McAleer et al. find the menu of inferences offered by Cooley and Leroy to be uninteresting because the models include no parameters for dynamics. McAleer et al. seem not to have been "conned." Why are they worried about the intelligence of the rest of us? Thus I think a global sensitivity analysis is neutral at worst with respect to dishonesty. After all, the finding that a data set does not admit a sturdy inference is news worthy of publication. On the other hand, current institutions clearly encourage, and have produced, either delusion or deceit.

### III. A Sugar Pill for a Nearly Terminal Patient

An epidemic of overparameterization debilitates our data analyses. We need strong medicine to combat this disease. I know a global sensitivity analysis is a bitter pill to swallow. But try it, I think it's going to make us all feel much better. Maybe not entirely well, but better anyway. The sugar pill that McAleer et al. offer has the pleasant taste of the familiar, but past experience suggests that it won't do any good.

Global sensitivity analysis can deal in principle with all varieties of parameters. "Extreme bounds analysis" is one example of a global sensitivity analysis. In order to make clear how the proposal of McAleer et al. compares with "extreme bounds analysis," we need to focus on the problem for which the "extreme bounds analysis" is intended, namely the choice of variables. The comments that follow apply equally well to

other parameter spaces, since the competing methodological approaches are the same regardless of the nature of the statistical assumptions selected by different parameters. In particular, the complaint that "extreme bounds analysis" doesn't deal with serial correlation, nonnormality, etcetera, is quite irrelevant. After all, it is hardly reasonable to complain that brain surgery can't cure a hangnail.

What McAleer et al. propose for the problem of choice of variables is a combination of backward and forward step-wise (better known as unwise) regression. The variables are divided into three groups, say  $x(1)$ ,  $x(2)$ , and  $x(3)$ . The first equation that is estimated includes all the variables from the sets  $x(1)$  and  $x(2)$  and excludes all the variables from the set  $x(3)$ . This "general model" is subjected to a sequence of tests to determine if subsets of the variables comprising  $x(2)$  can be omitted. The order for imposing the restrictions and the choice of significance level are arbitrary, though in some cases set by convention. Thus results a "preferred model." Then this preferred model is subjected to a battery of "specification error" tests to determine if variables in the subset  $x(3)$  should be included. Again the order and the levels of significance are arbitrary. So is the split into the subsets  $x(1)$ ,  $x(2)$ , and  $x(3)$ . What meaning should be attached to all of this?

# An Experimental Test of the Consistent-Conjectures Hypothesis

By CHARLES A. HOLT\*

A common way of analyzing multiperiod oligopoly models without dynamic interactions in the payoff structure is to compute a Nash equilibrium for each period taken separately. Many economists believe that behavior in a repeated market game cannot be predicted accurately with a period-by-period sequence of such "static" Nash equilibria, but an explicitly dynamic analysis can be extremely difficult unless the class of feasible dynamic strategies is restricted.<sup>1</sup>

There is an embarrassing multiplicity of alternative oligopoly "solutions" that are computationally less complex than game-theoretic approaches to multiperiod games. Many of these alternative solutions can be classified as conjectural variations models in which firms are assumed to conjecture that changes in their own decisions will induce reactions by other firms. These reactions are typically assumed to be characterized by

functions that are locally linear. Almost any configuration of decisions can be an equilibrium for some conjectured reaction functions, so these models have little empirical content unless the reaction functions themselves are determined endogenously.

Timothy Bresnahan (1981) has proposed a consistency condition that can often be used to determine specific conjectured reactions. Martin Perry provides a clear explanation of this consistency condition in the context of a duopoly in which firms' decisions are output quantities:

Each firm's first-order condition defines its profit-maximizing output as a reaction function on (1) the output of the other firm and (2) the conjectural variation about the other firm's response. Thus a conjectural variation by one firm about the other firm's response is consistent if it is equivalent to the derivative of the other firm's reaction function with respect to the first firm's output at equilibrium.

[1982, p. 197]

\*Department of Economics, University of Virginia, Charlottesville, VA 22901. This research was funded by the National Science Foundation. Laura Cohen, Brad Hauck, and Anne Villamil assisted in administering the experiments. Peggy Claytor assisted in the preparation of this manuscript. I am grateful to Dan Alger, Alfonso Novales, Robert Porter, Roger Sherman, and Joel Slemrod for comments on an earlier draft.

<sup>1</sup>James Friedman (1977) discusses the existence of Nash equilibria in a general class of reaction function strategies, but one cannot actually compute nondegenerate equilibrium reaction functions for even the simplest quadratic payoff structures. More severe restrictions on the strategy spaces can produce results. For example, Richard Cyert and Morris DeGroot (1970) use backward induction to compute Nash equilibrium sequences of outputs for a finite horizon duopoly model in which firms make output decisions in alternate periods. Friedman's "balanced temptation equilibrium" is a Nash equilibrium for a supergame in which firms choose contingent strategies that specify an equilibrium output level and a commitment to a permanent switch to the firm's static Cournot output if another firm increases its output above its equilibrium level. Edward Green and Robert Porter (1984) have analyzed a stochastic generalization of this balanced temptation equilibrium.

Many economists have found this notion of consistency to be appealing; Perry cites a large number of recent working papers on the theoretical properties of consistent-conjectures equilibria.

Although not explicitly dynamic, the consistent-conjectures equilibrium (CCE) approach initially seemed plausible to me because it predicts deviations from a static Nash equilibrium that are qualitatively consistent with the data reported in several published laboratory experiments with student subjects. These experiments, however, were not designed to provide a clear distinction between the CCE and other equilibrium concepts. This paper reports the results of an experiment designed specifically to test the consistent-conjectures hypothesis.

In Section I, the computation of a consistent-conjectures equilibrium is explained in the parametric context that is used to construct the experiment. Section II contains a discussion of how the payoff structures used in the previous laboratory experiments must be modified to permit a good test of the consistent-conjectures hypothesis. In Section III, I report the results of an experiment in which the theoretical predictions of the static Nash and consistent-conjectures equilibria are quite different. The data are clearly inconsistent with the CCE hypothesis. A related experiment is discussed in Section IV, and Section V contains a conclusion.

### I. The Consistent-Conjectures Hypothesis

The notion of a consistent-conjectures equilibrium is easily explained for a homogeneous-product duopoly in which variable costs are zero and industry demand is linear:  $p = A - B(x_1 + x_2)$ , where  $A > 0$ ,  $B > 0$ ,  $p$  denotes price, and  $x_i$  denotes the output of firm  $i$ . The profit function for firm  $i$  is  $x_i(A - Bx_1 - Bx_2)$ .

The first-order condition for the profit-maximization problem for firm  $i$  is

$$(1) \quad A - Bx_j - 2Bx_i - Bx_i\lambda_j = 0, \\ (i=1,2; j \neq i),$$

where  $\lambda_j \equiv dx_j/dx_i$ . The conjectural variation  $\lambda_j$  is assumed to be a constant.<sup>2</sup>

The two equilibrium outputs cannot be determined from the two equations in (1) unless the  $\lambda_j$  conjectural-variation parameters can be determined. To do this, Bresnahan uses a consistency condition that the actual profit-maximizing reaction of the  $i$ th firm's output to a change in  $x_j$  must be equal to the  $\lambda_i$  conjecture that characterizes the beliefs of firm  $j$ . Suppose that  $x_j$  changes by an amount of  $dx_j$ . Then Bresnahan computes the  $i$ th firm's profit-maximizing re-

sponse to this change by totally differentiating equation (1) to obtain

$$(2) \quad -Bdx_j - 2Bdx_i - B\lambda_j dx_i = 0, \\ (i=1,2; j \neq i).$$

Dividing (2) by  $dx_j$  and using the definition of  $\lambda_i$ , one can express (2) as

$$(3) \quad -B - 2B\lambda_i - B\lambda_j\lambda_i = 0, \\ (i=1,2; j \neq i).$$

It follows from the two equations in (3) that  $\lambda_i = \lambda_j = -1$ . Then (1) implies that  $x_i + x_j = A/B$ , so price and profits are zero for the consistent-conjectures equilibrium in this example.<sup>3</sup> Note that the industry output equals  $A/B$ , but the consistent-conjectures equilibrium outputs need not be equal in this example. This is because the graphs of the reaction functions that satisfy the consistency requirement in the example are overlapping straight lines.

<sup>3</sup>The CCE is a pair of outputs,  $x_1$  and  $x_2$ ; each firm knows the other's output with certainty and each firm calculates that a deviation will be unprofitable given the conjectured reaction of the other. The word conjecture itself connotes uncertainty, so it is natural to consider whether the derivation of the CCE in the text is affected by such uncertainty. Suppose that firm  $i$  is uncertain about the  $j$ th firm's reaction, and let the  $i$ th firm's conjectures about the other firm's reaction be represented by a random variable  $\tilde{\lambda}_j$  with expected value  $\lambda_j$ . Also,  $U_i(\cdot)$  indicates a utility function for firm  $i$ , and  $E_i\{\cdot\}$  indicates an expectation with respect to the  $i$ th firm's subjective distribution for  $\tilde{\lambda}_j$ . The first-order necessary condition for the maximization of expected utility is

$$E_i \left\{ U'_i \left( Ax_i - Bx_i x_j - Bx_i^2 \right) \right. \\ \left. \times \left[ A - Bx_j - 2Bx_i - Bx_i \tilde{\lambda}_j \right] \right\} = 0.$$

Note that the random variable  $\tilde{\lambda}_j$  appears only in the square brackets in the first-order condition. This is because the only uncertainty for firm  $i$  in this analysis is about the  $j$ th firm's reaction to a change in  $x_i$ . It follows from this observation and an assumption that  $U'_i(\cdot) > 0$  that the necessary condition above reduces to equation (1) in the text with  $\lambda_j = E_i\{\tilde{\lambda}_j\}$ .

<sup>2</sup>Bresnahan shows that the consistent conjectural variations will be constants when the profit function is quadratic.

The consistent-conjectures equilibrium concept can be applied when decision variables are prices and there are more than two firms. When the demand is linear, the product is homogeneous, and all firms have identical constant average costs, Morton Kamien and Nancy Schwartz (1983) show that the *CCE* price equals average cost and profits are zero regardless of the number of firms and regardless of whether the decision variables are prices or quantities. The predicted "competitive" result in all cases other than monopoly in this context is the basis of the design of the experiment discussed in Section III.

## II. Evidence from Previous Experiments

The first question that should be addressed is whether the popular static Nash equilibrium approach can explain behavior in multiperiod market experiments. F. Trenery Dolbear et al. (1968) reported data showing that behavior in multiperiod duopoly experiments deviates systematically from a static Nash equilibrium. Their subjects were students who chose prices simultaneously at the beginning of each "period." I will only discuss the "complete information" experiments in which subjects were given a payoff table that relates price choices to payoffs in pennies.<sup>4</sup> The subject's price choice determined a row in the table, and the average of the prices of the subject's competitors determined a column. The payoff entries in the table were computed with a quadratic profit function that resulted from a demand function with some product differentiation. Payoffs were rounded off to the nearest penny, and as a result, there were two symmetric Nash equilibria *in prices* at common prices of 17 or 18. If subjects had been able to collude, they could have maximized their

FIGURE 1. PRICE AVERAGES FOR THE 12 DUOPOLY EXPERIMENTS WITH COMPLETE INFORMATION REPORTED IN DOLBEAR ET AL.

joint profit by raising prices to 23. However, subjects were not able to communicate.

In each market experiment, the subjects made simultaneous price decisions 15 times, but they were not told the number of repetitions in advance. The average price for each experiment was obtained by averaging all prices for periods 8 through 12. There were 12 duopoly experiments with complete information, and the average price in each experiment is represented by a large dot on the horizontal price scale in Figure 1. The average price across all 12 experiments was 19.5, and Dolbear et al. concluded that these data indicate some tacit collusion in the sense that average prices and profits exceed the levels determined by a static Nash equilibrium in prices. Using the parameter values for the Dolbear et al. profit function, my earlier paper (1980) calculated the consistent-conjectures equilibrium price to be 19.2 in this context, and this is quite close to the observed price average.

Of course, these experiments were not designed to test the consistent-conjectures equilibrium, and there are several obvious ways in which the experiments do not provide a satisfactory test of this equilibrium concept. First, the subjects were required to make integer-valued price choices, but the *CCE* price was not an integer. Second, there is not much difference between the static Nash and the *CCE* prices. (This problem was even more severe for the oligopoly experiments with four subjects.) Finally, the word "competitors" in the subjects' payoff table may have suggested a particular type of behavior.<sup>5</sup>

<sup>4</sup>Dolbear et al. also considered an "incomplete information" condition. The average level of price choices was approximately the same under each information condition, but there was less dispersion in the incomplete information experiments. Their paper provides an interesting analysis of the effects of information and the number of sellers on the degree of tacit collusion.

<sup>5</sup>Roger Sherman warned me about using suggestive words, but I made the same mistake myself. In one of my pilot experiments, the term "oligopoly game" ap-

Next, consider the previous section's quantity-choice model with a linear market-demand function and a common, constant average cost. The symmetric, static Nash (Cournot) equilibrium when strategies are output *quantities* will result in a price that is greater than average cost and less than the price resulting from perfect collusion. In contrast, the consistent-conjectures equilibrium in this context will result in competitive outputs that drive price down to average cost and profits to zero. Therefore, homogeneous-product oligopoly experiments with quantity-setting subjects and constant average costs may provide a good opportunity to discriminate between the static Nash and the consistent-conjectures theories.

Lawrence Fouraker and Sidney Siegel (1963) reported the results of some complete-information duopoly and triopoly experiments with these characteristics. The columns in their payoff table corresponded to a subject's own output choices, which were integers between 8 and 32. The row was determined by the "Quantity produced by my competition," and this quantity could be between 8 and 64. Outputs between 33 and 64 were actually possible in the triopoly experiments because the "competition" consisted of two other subjects. For a duopoly, the collusive industry output was 30 (15 per subject), the theoretical Nash/Cournot industry output was 40 (20 per subject), and the competitive industry output was 60 (30 per subject). As indicated in the previous section, 60 is the output predicted by the CCE in this context. Fouraker and Siegel do not seem to have noticed that the rounding off of payoffs to the nearest half-penny resulted in two symmetric Nash equilibria: one

at an industry output of 40 and another at an industry output of 44.<sup>6</sup>

There were 16 complete-information duopoly experiments in this series (Experiment 10). Instead of averaging, Fouraker and Siegel used the subjects' decisions in the twenty-first period as an indicator of equilibrium behavior. The period-21 industry outputs were scattered fairly uniformly over the range from the collusive industry output (30) to the competitive (and CCE) industry output (60).<sup>7</sup>

The failure of outputs to rise to the CCE level in many markets may have been due to the fact that the profit was zero because price equaled average cost at this level. Subjects were told in the instructions that if they follow instructions and make "appropriate decisions," they "may earn an appreciable amount of money...but poor choices will result in small or no profit to you." Thus there is a possibility that the wording of the instructions made it less likely that the CCE result with zero profits would be observed. In my own experiments, subjects often appear to be frustrated after periods of very low profits, and such periods are usually followed by large output reductions that raise profits considerably.

There is, for me, a more compelling reason to expect that the outputs of 30 per duopolist would not be frequently observed in the Fouraker-Siegel duopoly experiments. Note that each subject is restricted to choose an output that is less than or equal to 32. The payoff table used by Fouraker and Siegel shows profits for values of the output of the "competition" between 8 and 64. In my opinion, each subject in the duopoly experiments was likely to realize that the outputs from 33 to 64 were irrelevant and, of course, no outputs above 32 were ever observed. If the output of the competition is less than 33, then it is a property of their table that any output below 28 will guarantee the subject a positive profit, regardless of what the competitor does. This truncation of the relevant payoff table caused by exogenous limits on

---

peared on the receipt form to be completed by subjects at the end of the experimental session. This form was passed out at the beginning of the experiment, and one of the subjects who noticed the oligopoly phrase later remarked that the phrase "gave it away." He remembered seeing an assertion in a textbook that oligopolists would collude to maximize joint profit. This subject was in the only duopoly pair (out of four pairs) that was able to reach the collusive output combination in the first market experiment. All data from this pilot experiment were disregarded, and the wording of the receipt form was changed.

<sup>6</sup>See the profit table in their appendix IV.

<sup>7</sup>The industry outputs in period 21 were 25, 30, 30, 32, 33, 38, 39, 40, 40, 44, 45, 49, 50, 55, 59, and 60.

output choices implies that the *CCE* profit of zero can be strictly dominated.<sup>8</sup> In particular, if both subjects were choosing outputs of 30 and earning no profit, then either one could cut output to 15 and earn at least 7.5 cents per period because the other seller's output cannot exceed 32.

This truncation argument does not apply in the triopoly experiments because the competition consists of two subjects, and there is no output decision a subject can make that will ensure a positive profit when each of the other two sellers chooses an output of 32. In fact, behavior in the triopoly experiments did seem to be much more competitive. The static Nash-equilibrium industry output for the triopoly was either 45 or 48.<sup>9</sup> The competitive and *CCE* output was 60, and the actual outputs in period 21 for the 11 triopoly markets were 40, 44, 46, 47, 51, 58, 59, 59, 62, 63, and 70. The median industry output of 58 is quite close to the *CCE* prediction of 60. An industry output of 58 with an approximately symmetric output configuration would result in earnings of only \$.02 per subject per period in 1960 dollars.

### III. An Experimental Test of the Consistent-Conjectures Hypothesis

It follows from the above discussion that an experiment designed to test the consistent-conjectures hypothesis should have the following characteristics: (a) potentially suggestive words such as "competitors" should not appear in the instructions and payoff tables, (b) the *CCE* decisions should be integers, (c) the profit per hour per subject at the *CCE* should be reasonable, and

(d) there should be no decision a subject can make that ensures a profit that will always exceed the *CCE* profit level.

#### A. The Payoff Structure

Bresnahan's original analysis of the *CCE* was for a duopoly in which firms' decision variables are quantities. As indicated in the previous section, models with quantity-setting duopolists are convenient because it is easy to choose market parameters that yield very distinct predictions for the Cournot and the consistent-conjectures equilibria. The experiment reported in this section involved subjects who chose output quantities.<sup>10</sup> Subjects' profits depend on these output choices, and the Profit Table (Table 1) was computed from equation (1) with  $A=12$  and  $B=1/2$ . In addition, \$.45 was added to each of the resulting profit entries. A calculus argument can be used to show that the outputs in a symmetric, collusive equilibrium are 6 per subject and the static Nash/Cournot outputs in a symmetric, collusive equilibrium are 8 per subject. Outputs are integer valued in the experiment, but this does not affect the collusive and Nash equilibria. For example, if both subjects choose outputs of 8, then a unilateral, integer-valued deviation will not increase a subject's profit given the Cournot conjecture. Because of the rounding off of profits to the nearest penny, there are also

<sup>8</sup>This is a serious limitation of the Fouraker-Siegel experiments because the main objective of these experiments seemed to have been to determine the proportions of duopoly pairs which could be best classified as either collusive, Cournot, or competitive. The competitive or "rivalistic" outputs of 30 probably did not have a chance. In a different context, James Murphy (1966) has shown that truncation of the payoff table can have a major effect on experimental results.

<sup>9</sup>The output of 45 was implied by the profit-function parameters, but outputs of 16 for each subject constituted a Nash equilibrium for the payoff table that was used.

<sup>10</sup>In modeling *actual* market situations, the choice of how to model firms' strategies (as output quantities, prices, or something else) is very important. The specification of strategies is not arbitrary. In some markets, firms choose catalogue prices independently and then produce to order. Firms in such markets choose prices independently, but quantities may depend on rivals' prices, so the appropriate decision variable is price. In other markets, key production decisions are made independently in advance, but the price at which a firm's output can be sold depends on other's quantities. Those who use models with quantity-setting firms are presumably considering this type of market. Bresnahan's exposition is for quantity decisions, and it is appropriate to conduct an experimental test of the *CCE* with quantity decisions even if one believes that models with quantity-setting firms are unreasonable for most markets. A useful equilibrium concept should have the property that it yields good predictions for both specifications of decision variables, price and quantity.

TABLE 1—PROFIT TABLE<sup>a</sup>  
Your Output

<sup>a</sup>Shown in pennies

two asymmetric Nash equilibrium configurations: one with outputs of 7 and 9 and another with outputs of 6 and 10. In all cases, however, the industry output is 16 in a Nash equilibrium.

It follows from the calculations in Section I that the consistent conjecture is -1 in this context, and any combination of outputs that sum to 24 constitutes a CCE. These output combinations lie on the diagonal with \$.45 profits in the Profit Table. Starting on the diagonal, if one subject increases or decreases output by an integer amount, the other subject is conjectured to make an equal output change in the opposite direction. Thus the new output pair would again be on the \$.45 profit diagonal, so the deviation would not increase the subject's profit, given the consistent conjecture.

The collusive industry output of 12 yields earnings of \$.81 per subject, the static Nash/Cournot industry output of 16 yields earnings of \$.77 per subject in the symmetric case, and the CCE industry output of 24 yields earnings of \$.45 per subject. The experiment was not designed to distinguish noncooperative and collusive behavior, but neither of these modes of behavior yields outputs and profits that are close to those

implied by the consistent-conjectures hypothesis in this context.<sup>11</sup> The high output levels (13 to 22) were included so that no output decision would guarantee a profit that exceeds the CCE level of \$.45 per period.

The \$.45 can be thought of as a normal rate of return when price equals average cost and economic profits are zero. Subjects were also given an initial stake of \$.50 to cover any early losses. The announcement used to solicit subjects stated: "Although earnings cannot be predicted precisely, they will average about \$6 per hour." The experiments were run at a pace of about 13 periods per hour, so the \$.50 stake and the CCE profit of \$.45 per period would result in earnings of about \$6 per hour.

<sup>11</sup>An increase in the *A* parameter will increase the spread between the Cournot and collusive output decisions, but this will increase profits and make the experiments more expensive to run. The use of a fixed cost to lower all profit entries is not possible because the profit at the consistent-conjectures equilibrium should be sufficiently positive. A reduction in the *B* parameter will also increase the spread between the Cournot and collusive outputs, but the resulting flatness in the payoff structure results in multiple Cournot equilibria when profits are rounded off to the nearest penny.

### B. Subjects and Procedures

The subjects were students in introductory and intermediate economics classes at the University of Minnesota. The instructors in these classes had not discussed experimental economics or formal oligopoly theory. The subjects had no previous experience with economics experiments.

Subjects were given about 10 minutes to read the instructions, which are available from the author on request. An additional paragraph in the instructions was read aloud by one of the people conducting the experiments. The purpose of this additional paragraph was to convince the subjects that the "other seller" in "a nearby room" was actually a person (not a computer).

The subjects were also given a Decision Sheet that revealed the "position number" of the other seller in that subject's market. The other sellers were seated in a separate room. First there was a "trial period," in which subjects marked their "output choices" on their Decision Sheets. Then they were told the output choice of the other seller, and they were asked to use the payoff table to compute both their own and the other seller's profit. This allowed us to check the subjects' understanding of the payoff table without suggesting anything by the use of hypothetical outputs to illustrate the computation of profits. In each subsequent period, we collected the Decision Sheets, computed profits, and paid the profits earned before the beginning of the next period. Subjects in the same room were spaced so that they would not be able to see exactly how much money others were earning. Subjects were also invited to write brief "explanations" of their decisions on their Explanation Sheet.

Subjects will naturally be curious about when the experiment will end, and I think the best way to deal with this is to be explicit about the stopping rule. A random stopping rule was used to avoid end effects. Subjects were told that there would be at least 7 periods and that there was a probability of  $1/6$  that period 7 and each following period would be the final period. The final period was determined by a six on the throw of a die, but we used the same sequence of die

throws for all subjects. The throw of the die was recorded on the Decision Sheet.

There were 24 subjects that will be labeled  $S1$ ,  $S2$ , etc. There were 12 initial pairings of subjects, and all subjects participated in a "first market" that was terminated by a throw of the die after 13 periods for all pairs. In order to check for experience effects, 16 of these subjects were rematched and given a new Decision Sheet with the new position number of the other seller. A different sequence of throws of the die was used, and this "second market" was terminated after 9 periods.

### C. The Data

The output choices for the 24 subjects who participated in the first market are shown in Table 2, and choices for the 16 experienced subjects who participated in the second market are shown in Table 3. The final-period industry inputs ( $x_1 + x_2$ ) for all duopoly pairs are plotted along the market demand curve in Figure 2. There was some collusive behavior resulting in outputs of 6 per subject, and there was rivalistic behavior resulting in industry outputs greater than the static Nash/Cournot industry output of 16. Regardless of whether the first-market and second-market data are considered separately or together, the mean and median (or medians) of the final-period industry outputs are between 14 and 16. Earnings averaged about \$8.50 per subject per hour.

The data are clearly inconsistent with the CCE prediction of an industry output of 24, in my opinion. None of the final-period industry outputs exceed 21. There was only one pair of subjects ( $S7$  and  $S2$  in the second market) with combined outputs that were often closer to the CCE level of 24 than to the static Nash/Cournot level of 16. The occasional high outputs of other subjects usually appear to be attempts to punish a rival for not reducing output. For example, subject  $S3$  had been in a collusive duopoly in the first market, but  $S3$  was not able to induce  $S6$  to collude in the second market. Apparently frustrated,  $S3$  increased output from 6 to 19 in period 4 and then returned to 6 in period 5.

<sup>a</sup>Subject S1 was paired with S4, S3 with S6, etc.

A statistical analysis should begin with a consideration of why some duopoly pairs are more collusive than others. Variations in market outcomes may be due to variations in variables not included in the oligopoly models discussed above, variables such as individuals' willingness to experiment with output changes. Suppose that individuals'

characteristics are independent drawings from some population of possible characteristics. Then it is natural to think of final-period industry outputs for either the first or second market (not both together) as being independent realizations of a random variable. In the following discussion, the 8 final-period industry outputs in the second mar-

FIGURE 2. FINAL-PERIOD INDUSTRY OUTPUT FOR DUOPOLY MARKETS

Note: ○ First-market duopoly output  
● Second-market duopoly output

ket will be denoted by  $Q_1, Q_2, \dots, Q_8$ , and the vector of these outputs will be denoted by  $\bar{Q}$ . Consider a family of hypotheses of the form:  $Pr\{Q_i < y\} \leq 1/2$  for some  $y > 21$ ;  $i = 1, \dots, 8$ . This family includes a hypothesis that the median of the industry outputs is 24, the theoretical prediction of the consistent conjectures equilibrium. Let  $H_y$  denote a particular hypothesis in this family that corresponds to a particular value of  $y$ . It can be seen from a binomial probability table that  $Pr\{\bar{Q} | H_y\} \leq .0039$  because all 8 industry outputs are less than 21. However, a rejection of  $H_y$  using a classical hypothesis test would be misleading if there were no other hypothesis that is reasonable given the data observed. But there are many reasonable alternatives in this case. For example, consider a hypothesis  $H_{16}$ :  $Pr\{Q_i < 16\} = 1/2$ ,  $i = 1, \dots, 8$ . This hypothesis implies that a median of the distribution is 16, the theoretical prediction of the static Nash equilibrium. It follows from simple binomial probability calculations that  $Pr\{\bar{Q} | H_{16}\} = .2734$ , so the likelihood ratio is greater than  $.2734/.0039$ . If the posterior probabilities for  $H_{16}$  and  $H_y$  are denoted by  $Pr\{H_{16} | \bar{Q}\}$  and  $Pr\{H_y | \bar{Q}\}$ , respectively, then the ratio  $Pr\{H_{16} | \bar{Q}\} / Pr\{H_y | \bar{Q}\}$  is more than 70 times as great as the corresponding ratio of prior probabilities. A Bayesian analysis of the final-period outputs for the first-market experiments yields even stronger conclusions.

#### IV. A Single-Period Duopoly Experiment

The experimental design discussed above induces an infinite horizon in which the probability of termination determines the tradeoff between profit in the current period and profit in the future. In other words, the probability of termination determines the rate of which profits are discounted. If the probability of termination is low enough, subjects may be willing to make unprofitable output reductions in the hope of inducing the other seller to cut output in the future.

Roughly speaking, the behavior in the experiments discussed in Section III can be categorized as either collusive or noncooperative. I expected that an increase in the termination probability from  $1/6$  to 1 would result in no collusion. From a game-theoretic perspective, the static Nash equilibrium is appropriate for single-period games in which subjects are not able to use strategies that are contingent on decisions made in previous periods. Thus, single-period experimental markets would give the static Nash equilibrium its best chance. These markets may also yield even more rivalistic behavior.

I conducted one set of experiments with 12 subjects who participated in a series of 11 single-period duopoly markets with the same payoff table that was used in the multiperiod experiments. The subjects were drawn from a pool of people who had previous experience with a different series of duopoly experiments with different payoff tables. Six subjects were seated in each of two large rooms, and subjects were spaced so that they were unable to determine the "position number" of any other subject in their own room. A research assistant was present in each room at all times. The instructions for these single-period experiments are available from the author on request.

The experiment began with a trial period in which profits were computed but not paid. This was followed by 10 single-period markets. The aggregate data on individual choices for these markets are graphed in Figure 3, and data for particular subjects and their rivals are given in Table 4. The output choices are initially quite diverse, but

TABLE 4—SINGLE-PERIOD EXPERIMENTS: SUBJECTS' OUTPUT CHOICES

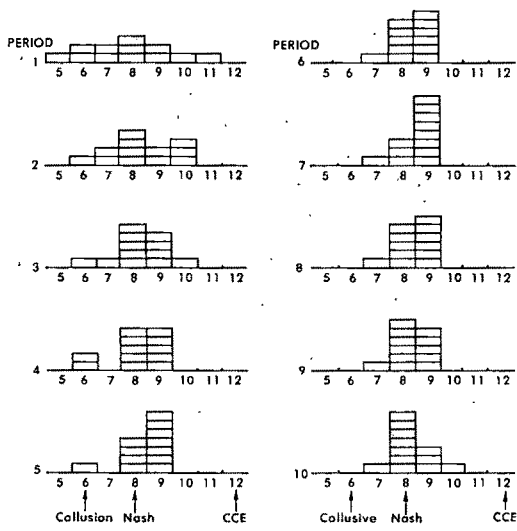

FIGURE 3. FREQUENCY OF INDIVIDUAL OUTPUT CHOICES IN THE SINGLE-PERIOD MARKET EXPERIMENT

by period 7 two-thirds of the subjects are choosing outputs of 9. This is followed by a trend toward the symmetric Nash/Cournot outputs of 8, and 7 of the 12 subjects choose 8 in the final period. As expected, there was no successful collusion in the later periods of this experiment.

The frequency of rivalistic outputs of 9 in the intermediate periods is interesting. First, note that 9 is not very far from a Nash equilibrium in terms of profits. For the range of sellers' outputs in the final periods, any seller with an output of 9 could only increase

profit by \$.01 by switching from 9 to 8. If the outputs are 9 for one seller and 8 for the other, the profit is \$.76 for the high-output seller and \$.73 for the other. At outputs 8 and 8, they each make \$.77. To see why some individuals were willing to give up a penny of profit per period, I looked at the explanation sheets. There were several rivalistic comments about relative profits. For example, one person remarked: "Only a \$.01 loss occurs producing at 9 instead of 8. This keeps the other firm's profits down." This subject did switch to 8 in the final period. Another subject, the only one to have an output of 10 in the final period, remarked in period 4 that when paired "...against a firm with lower output than mine, I make the larger profit, 9 is an interesting number to produce...." However, it is clear that no subject's objective was to maximize the difference between profits; if the other seller produces either 8 or 9, then an output of 12 will maximize the difference between a subject's own profit and that of the other seller. In retrospect, there probably would have been less variability in the data if subjects in these experiments had not been given the complete information necessary to compute the other sellers' profit.

V. Conclusion

In this paper, I compare the theoretical predictions of the consistent-conjectures hypothesis with data for individuals' behavior in several laboratory experiments. In all ex-

periments discussed, subjects simultaneously choose either price or quantity in a sequence of market periods, and subjects are given payoff tables that provide "complete information" about the relationship between decisions and profits for all participants.

My interpretation of the previously published experimental results is—the consistent-conjectures hypothesis provides a good explanation of the price choices made by subjects in the Dolbear et al. experiments, but the predictions of the consistent conjectures and static Nash equilibria are quite close. The predictions of these two equilibria are not close for the Fouraker-Siegel experiments with quantity-setting subjects. The CCE does not provide a good explanation of the output choices in the Fouraker-Siegel duopoly experiments, but its predictions look more reasonable in the triopoly experiments. The poor performance of the CCE in the duopoly case may have been because subjects' profits were zero at the CCE and there were other output choices a duopolist could make that would ensure a strictly positive profit.

This paper reports the results of a new set of duopoly experiments with complete information in which payoffs are positive at the CCE, and there is no decision that can guarantee a profit that exceeds the CCE profit. The consistent-conjectures equilibrium does not provide good predictions in these experiments. The data are more consistent with the Cournot equilibrium, although several duopoly pairs managed to achieve perfect collusion tacitly. Thus, there is at least one simple payoff structure (with homogeneous products, linear demand, and constant average variable costs) in which the CCE predictions are clearly inaccurate.

There are, however, several questions a skeptical reader may wish to consider. First, can laboratory experiments with individual decision makers be used to evaluate theories of the behavior of business firms? Many economists will give a negative answer, but I see nothing in the computation of a consistent-conjectures equilibrium that suggests that the arguments apply to business organizations but not to individuals. One obvious

difference between businessmen and the student subjects is that businessmen have more experience with the markets in which they operate. But when experience has been shown to have a significant impact on behavior in experiments, the effect has been to increase the frequency of collusion.<sup>12</sup> Increased collusion in the experiments reported here would further skew the data away from the "competitive" CCE output prediction.

A second issue is whether the inaccuracy of the CCE prediction derived in Section I is due to something other than the inconsistency of conjectures. In particular, could it be the case that conjectures are consistent but that subjects are maximizing something other than profit? There was a slight tendency toward rivalistic behavior in the single-period experiment, so one may wish to consider an objective function  $R_i$  for the  $i$ th subject of the form:  $R_i = \pi_i + w_i \pi_j$ ; ( $i=1,2$ ;  $j \neq i$ ); where  $\pi_i = x_i(A - Bx_1 - Bx_2)$ ,  $-1 < w_i < 1$ . If the  $w_i$  parameter is zero the subject is a profit maximizer, and as the  $w_i$  parameter approaches  $-1$  the subject becomes very rivalistic and seeks to maximize the difference in profits. The first-order condition analogous to (1) is

$$(4) \quad A - Bx_j - 2Bx_i - Bx_i\lambda_j + w_i[(A - Bx_i - 2Bx_j)\lambda_j - Bx_j] = 0.$$

The consistency condition analogous to (3) is

$$(5) \quad -B - 2B\lambda_i - B\lambda_j\lambda_i + w_i(-B - 2B\lambda_j - B\lambda_j\lambda_i) = 0, \\ (i=1,2; j \neq i).$$

The two equations in (5) imply that  $\lambda_i = \lambda_j$

<sup>12</sup>See Charles Plott (1982) for a discussion of the relationship between experience and collusion in laboratory experiments. Plott also has an excellent summary of the arguments for and against using laboratory experiments to test industrial organization theories.

$= -1$ , so the consistent conjectures are not affected by the possible rivalistic nature of objectives. These conjectures and (4) imply that  $x_i + x_j = A/B$ , so the CCE industry output is unchanged. Thus the inaccuracy of the CCE predictions in this context cannot be attributed to the possibility of nonzero values of the  $w_i$  parameters.

Finally, there is the question of the choice of the rule for ending the experiments. In experiments reported in this paper, the stopping rule was explicit, and a termination probability of  $1/6$  was used in the multi-period experiment. The choice of this particular termination probability was arbitrary because there is no parameter in the theoretical analysis of consistent-conjectures equilibria that corresponds to a termination probability nor is there a discount rate. The CCE concept is not explicitly dynamic; the timing of output deviations, initial reactions, and subsequent reactions by the deviant is not clear. As Perry points out: "The conjectural variation model is a simple static representation of the potentially complex dynamics of an oligopoly, and consistency as defined [in a CCE]...is the simplest adequate static condition for rational behavior in such a model" (p. 200).

The CCE did not provide a satisfactory representation of the dynamics in experimental markets with a termination probability of  $1/6$ . I would expect to observe more collusion and less rivalistic behavior if the termination probability were even less than  $1/6$ . For termination probabilities that exceed  $1/6$ , I would expect behavior to conform more closely to the predictions of the static Cournot model. In the single-period market experiments with a termination probability of 1, the Nash/Cournot equilibrium provided accurate predictions, and there was no tendency to collude.

# Rational Expectations and the Limits of Rationality: An Analysis of Heterogeneity

By JOHN HALTIWANGER AND MICHAEL WALDMAN\*

A recurring controversy in economic thought concerns the conflict between the assumption of rationality and the fact that economic agents have limited capacities to process information.<sup>1</sup> For example, this conflict was a factor in the marginalist debate of the 1940's, and is a factor in the challenge to standard economic theory of Herbert Simon and his followers.<sup>2</sup> Recent refinements to the concept of rationality have brought this conflict into sharper focus. That is, rationality no longer simply implies that behavior is determined by the maximization of a well-ordered function. Rather, it now typically implies the expected utility hypothesis of behavior under uncertainty, and the rational expectations hypothesis for the formation of expectations.

Those individuals who have attempted to provide alternatives to the rationality assumption have in general paid close atten-

tion to descriptive realism. In other words, the alternative models of the decision-making process which have been provided tend to match, at least to a first approximation, the manner in which decisions are reached in the real world. One aspect of the real world, however, has generally been ignored in these alternative models. Specifically, these models, as well as most models that contain the rationality assumption, ignore the idea that agents tend to be heterogeneous in terms of information-processing abilities. That is, some agents in our economy are able to process information in a very sophisticated manner, while others are much more limited in their capabilities. In the present paper we attempt to investigate the ramifications of this type of heterogeneity. We do this by analyzing two simple models wherein agents differ in terms of their ability to form expectations. To keep the analysis tractable, in each of the models it is assumed that only two types of agents exist. Agents of the first type have unlimited abilities to form expectations, and thus have correct or rational expectations. These agents will be referred to as "sophisticated." Agents of the second type are limited in their ability to form expectations, and thus have incorrect expectations. These agents will be referred to as "naive." Our goal is to characterize equilibria under this type of heterogeneity, and in the process identify situations in which sophisticated agents have a disproportionately large effect on equilibrium, and situations in which naive agents have a disproportionately large effect.<sup>3,4</sup>

We thank Robert Clower, Ian Novos, Mark Plant, Earl Thompson, Susan Woodward, the participants of the Theory Workshop at UCLA, and two anonymous referees for helpful comments, and the Foundation for Research in Economics and Education for financial support. We accept responsibility for any remaining errors.

<sup>1</sup>This conflict does not mean that agents who have limited capacities to process information are not rational under some broad definition of the term, but rather that they are not rational under the literature's definition of the term "rationality." Note, this limited ability to process information is sometimes referred to as bounded rationality. However, because of its frequent association with the related concept termed satisficing, we will refrain from using the term bounded rationality in this paper.

<sup>2</sup>References to the marginalist debate of the 1940's include Robert Hall and Charles Hitch (1939) and Fritz Machlup (1946). References to the work of Simon and his followers include Simon (1959), Richard Cyert and James March (1963), Oliver Williamson (1975), and Richard Nelson and Sidney Winter (1982). See also Roy Radner (1975) for explicit modeling of Simon's ideas.

<sup>3</sup>The term equilibrium in this paper simply refers to the outcome of the model, given an exogenous specification for the expectations of the naive.

<sup>4</sup>Three recent papers which do consider the type of heterogeneity we consider are John Conlisk (1980), Thomas Russell and Richard Thaler (1985), and George

One might question our approach of looking at the equilibria of models that contain agents who have incorrect expectations. Some might argue that, since models with learning frequently converge to rational expectations equilibria, in the types of models we are investigating it only makes sense to investigate rational expectations equilibria.<sup>5</sup> We disagree with this argument for three reasons. First, there are many important economic situations that are not repeated for the agents involved, and for these situations the fact that learning models converge to rational expectations equilibria is irrelevant. Examples include the career choice problem faced by the young, and the related decision concerning whether or not to attend college. Second, there are many economic situations that do repeat; however, for each repetition there is a proportion of agents who have no previous experience with the situation. An example of this is the problem consumers face when they must choose among different computer hardware systems. That is, for each new generation of computers there is likely to be a proportion of buyers who have not previously bought a computer system. Third and finally, empirical evidence does not support the practice of restricting attention solely to rational expectations equilibria (see Kenneth Arrow, 1982, for a survey of this evidence).

In Section I, each agent in the economy is faced with the problem of choosing a single path from a set of two, where the paths exhibit congestion effects. By congestion effects we mean that for any agent  $i$ , the higher is the number of other agents who choose the same path as the one chosen by agent  $i$ , the less well off is agent  $i$ . The model

of this section might best be thought of as a stylized model of either the problem of career choice, or the problem of choosing a road with which to reach some final destination. In this setting we find that sophisticated agents have a disproportionately large effect on equilibrium. That is, congestion effects cause the equilibrium to more closely resemble what occurs when all agents have rational expectations than would be suggested by the relative number of sophisticated agents and naive agents in the population.

The intuition behind this result is as follows. Because of incorrect expectations, the allocation of naive agents to paths is biased relative to how agents are allocated when there are no naive agents. Sophisticated agents, on the other hand, anticipate this behavior and, because of congestion effects, compensate by having their behavior being biased in an exactly opposite manner. Or overall, sophisticated agents have a disproportionately large effect on equilibrium because sophisticated agents anticipate the bias of the naive, and compensate in a way which tends to nullify this bias.

In Section II we again look at the model developed in Section I, but we change the specification so that the model exhibits the reverse of what we previously referred to as congestion effects. In other words, for any agent  $i$ , the higher is the number of other agents who choose the same path as the one chosen by agent  $i$ , the *better* off is agent  $i$ . We will say that situations which exhibit this type of property exhibit synergistic effects. Contrary to what we found in Section I, here it is the naive agents who have a disproportionately large effect on equilibrium. That is, synergistic effects cause the equilibrium to more closely resemble what occurs when all agents are naive than would be suggested by the relative number of sophisticated agents and naive agents in the population.

The intuition behind this result is similar to the intuition given above. Because of incorrect expectations, the allocation of naive agents to paths is again biased relative to how agents are allocated when there are no naive agents. Furthermore, sophisticated agents again anticipate this behavior, but because there are synergistic effects, they now

---

Akerlof and Janet Yellen (1985). The main difference between our paper and these papers is that we focus on the conditions that lead to sophisticated agents having a disproportionately large effect on equilibrium, and also on the conditions that lead to the naive having a disproportionately large effect—an issue not addressed in the above papers.

<sup>5</sup> Examples of papers wherein learning causes convergence to rational expectations equilibria include Cyert and Morris DeGroot (1974), and Stephen DeCanio (1979).

compensate by having their behavior being biased in a manner *similar* to the bias of the naive. Or overall, naive agents have a disproportionately large effect on equilibrium because sophisticated agents anticipate the bias of the naive, and compensate in a way which tends to reinforce this bias.

In Section III we consider a simple model of the chain-store paradox (see Richard Selten, 1978; David Kreps and Robert Wilson, 1982; and Paul Milgrom and John Roberts, 1982, for papers on this issue). The key property of this model is that it is one where reputation effects are potentially important. The basic result that emerges from the analysis of Section III is that, when reputation effects are potentially important, it is possible for either type of agent to be dominant. That is, under some parameterizations sophisticated agents have a disproportionately large effect on equilibrium, while for other parameterizations the naive agents are the ones who have the disproportionately large effect.

One might ask what conclusions can be drawn from the above results with regard to the common practice of assuming that all agents in the economy have rational expectations. Our feeling is that, since agents in the real world are obviously heterogeneous in terms of information-processing abilities, the practice of assuming rational expectations is relatively more defensible when agents who can process information in a very sophisticated manner have a disproportionately large effect on equilibrium. Thus, our results suggest that for the analysis of situations that exhibit congestion effects, there are relatively strong justifications for assuming rational expectations. However, for the analysis of situations that exhibit either synergistic effects or the possibility for reputation formation, the practice of assuming rational expectations would seem to be less defensible.

### I. Choosing Paths with Congestion Effects

Here we consider the problem of agents choosing between two paths, where the paths exhibit congestion effects. By congestion effects we mean that for any agent  $i$ , the higher is the number of other agents who

choose the same path as the one chosen by agent  $i$ , the worse off is agent  $i$ . Examples of real world choice situations that exhibit congestion effects are the career choice problem faced by the young, the related decision concerning whether or not to attend college, and the commuter's problem of choosing between alternate routes.

As indicated above, each agent must choose between two paths, which we denote as  $A$  and  $B$ . Furthermore, it is assumed that this choice of paths is an irreversible choice, and is made simultaneously by all the agents in the population. If agent  $i$  takes path  $A$ , then his utility equals  $r_A(N_A, \theta_A) - c_i$ . Similarly, if agent  $i$  takes path  $B$ , then his utility equals  $r_B(N_B, \theta_B) - (C - c_i)$ . The term  $N_A(N_B)$  denotes the total number of agents who choose path  $A(B)$ , while  $\theta_A$  and  $\theta_B$  are random variables, the realizations of which are unknown at the date the participation decision is made. It is further assumed that agents are expected utility maximizers, which means that we need only be concerned with  $f_A(N_A)$  and  $f_B(N_B)$ , where  $f_A(N_A) = E_{\theta_A}[r_A(N_A, \theta_A)]$  and  $f_B(N_B) = E_{\theta_B}[r_B(N_B, \theta_B)]$ . Formally, assuming that the paths exhibit congestion effects means assuming  $f'_A \leq 0$  and  $f'_B \leq 0$ , where one of these inequalities is everywhere strictly negative. Note,  $c_i$  and  $(C - c_i)$  can be interpreted as representing either agent  $i$ 's underlying preferences for the two paths, or the costs incurred by agent  $i$  in taking each path. This latter interpretation matches well with our description of the model as a model of commuting. That is, when thought of as a model of commuting,  $c_i$  can be interpreted as the distance between agent  $i$ 's housing location and path  $A$ 's entry ramp, while  $(C - c_i)$  can be interpreted as the distance between the housing location and path  $B$ 's entry ramp.

The population consists of a continuum of agents who vary in terms of their values for  $c_i$ . In particular, the distribution of  $c_i$ 's in the population is described by a density  $g(c_i)dc_i$  defined on the interval  $[0, C]$ , where  $g(\cdot)$  is continuously differentiable and non-zero everywhere in the specified interval. There are two types of agents in this population: sophisticated and naive. It is assumed that a proportion  $p$  of the total population is

sophisticated,  $0 \leq p \leq 1$ , while a proportion  $(1-p)$  is naive. Formally, this translates into assuming that the distribution of  $c_i$ 's in the population of sophisticated (naive) agents is described by a density  $h(c_i)dc_i$  ( $j(c_i)dc_i$ ) defined on the interval  $[0, C]$ , where  $h(\cdot) = pg(\cdot)$  ( $j(\cdot) = (1-p)g(\cdot)$ ) everywhere in this interval. Note, we also assume  $f_A(0) > f_B(\int_0^C g(c_i)dc_i) - C$  and  $f_B(0) > f_A(\int_0^C g(c_i)dc_i) - C$ . This pair of assumptions guarantees that, as long as  $0 < p \leq 1$ , the equilibrium will be characterized by some agents taking each path.

The only aspect of the model that remains to be specified concerns expectations. Expectations are relevant in that, prior to deciding which path to take, each agent forms expectations concerning the resulting value for  $f_A(N_A) - f_B(N_B)$ . Sophisticated agents are assumed to have unlimited abilities to form expectations, and thus have correct or rational expectations concerning the resulting value for  $f_A(N_A) - f_B(N_B)$ . On the other hand, naive agents are limited in their ability to form expectations, but all have the same incorrect expectation concerning  $f_A(N_A) - f_B(N_B)$ , where  $V$  denotes this expectation.<sup>6</sup>

The above assumption that all naive agents have the same incorrect expectation is basically a simplifying assumption. There is, however, a reason for assuming that all naive agents have similar biases in their expectations. That is, in the studies of cognitive psychologists it is frequently the case that the expectational errors of agents are correlated across individuals (see Daniel Kahneman, Paul Slovic, and Amos Tversky, 1982).

The rest of this section consists of an analysis of the above model.<sup>7</sup> Let  $D = (f_A(N_A) - f_B(N_B) + C)/2$  and  $D^n = (V + C)/2$ . Given that sophisticated agents have rational expectations, sophisticated agent  $i$

will choose path  $A(B)$  when<sup>8</sup>

$$(1) \quad c_i < (>) D.$$

On the other hand, given the expectations of the naive, naive agent  $i$  will choose path  $A(B)$  when

$$(2) \quad c_i < (>) D^n.$$

Equations (1) and (2) in turn yield<sup>9</sup>

$$(3) \quad N_A = \int_0^D pg(c_i)dc_i + \int_0^{D^n} (1-p)g(c_i)dc_i$$

$$(4) \quad N_B = \int_D^C pg(c_i)dc_i + \int_{D^n}^C (1-p)g(c_i)dc_i$$

Let  $N_A^s(N_B^s)$  denote the number of agents who choose path  $A(B)$  when all are sophisticated (i.e.,  $p=1$ ),  $N_A^n(N_B^n)$  denote the number of agents who choose path  $A(B)$  when all are naive (i.e.,  $p=0$ ), and  $D^s$  denote the value for  $D$  when  $p=1$ . Note, we refer to the equilibrium when  $p=1$  as the pure rational expectations equilibrium, and the equilibrium when  $p=0$  as the pure limited rationality equilibrium. We now proceed to our first proposition (note: all proofs are relegated to the Appendix).

**PROPOSITION 1:** *If  $0 < p < 1$  and  $N_A^s \geq N_A^n$ , then  $N_A \geq pN_A^s + (1-p)N_A^n$ . Note, this also implies that if  $0 < p < 1$  and  $N_B^s \geq N_B^n$ , then  $N_B \geq pN_B^s + (1-p)N_B^n$ .*

The interpretation of Proposition 1 is straightforward. When agents are heterogeneous in terms of information processing abilities (i.e.,  $0 < p < 1$ ), sophisticated agents have a disproportionately large effect on the number of agents who take each path. That is, in terms of the number of agents who take

<sup>6</sup> Given that agents are risk neutral,  $V$  can be interpreted as the mean of a distribution that describes the naive agents' expectations.

<sup>7</sup> Our analysis derives properties which an equilibrium for this model must display. In a mathematical supplement available from the authors upon request, we demonstrate that, for the specifications of both Section I and Section II, an equilibrium exists and is unique.

<sup>8</sup> Because it concerns a set of agents whose weight is zero, we need not specify what happens when  $c_i = D$ .

<sup>9</sup> Equations (3) and (4) are written for the case  $0 \leq D^n \leq C$ .

each path, the equilibrium more closely resembles the pure rational expectations equilibrium than would be suggested by the relative number of sophisticated agents and naive agents in the population. The next step of the analysis is to consider the social welfare aspects of our model.

Social welfare, denoted  $W$ , is here defined as the sum of the utilities of all the agents in the population. Furthermore, to stay consistent with previous notation,  $W^s$  will denote social welfare when  $p=1$  and  $W^n$  will denote social welfare when  $p=0$ . In terms of social welfare, we feel there are two questions which deserve to be addressed. The first question is analogous to the question addressed in Proposition 1. That is, how does  $W$  compare with  $\bar{W}$ , where  $\bar{W} = pW^s + (1-p)W^n$ ? The second question is, how do the reactions of the sophisticated agents, in response to the behavior of the naive, affect social welfare? That is, do the reactions of the sophisticated tend to drive social welfare towards  $W^s$  or towards  $W^n$ ? To answer this second question we compare  $W$  with  $\hat{W}$ , where  $\hat{W}$  is the social welfare that results when sophisticated agents behave as if  $D$  equals  $D^s$ , while naive agents behave as before. In other words,  $\hat{W}$  is the social welfare that results when, even though agents are heterogeneous, sophisticated agents behave as if all agents were sophisticated.

Before proceeding to our social welfare proposition, it is necessary to define some terms concerning the optimal allocation of agents to paths. Note, because congestion effects create externalities, the equilibrium when all agents are sophisticated does not in general yield an optimal allocation of agents to paths. Suppose there was a social welfare-maximizing government that was all knowing, and that could direct the actions of all the agents in the population. We denote as  $N_A^0(N_B^0)$  the total number of agents such a government would send to path  $A(B)$ .

We can now make comparisons between  $W$  and our two social welfare benchmarks.

**PROPOSITION 2:** Suppose  $f_A'' \leq 0$ ,  $f_B'' \leq 0$ ,  $0 < p < 1$  and that either  $N_A^s, N_A^n \leq N_A^0$  or  $N_A^s, N_A^n \geq N_A^0$ . If  $W^s > W^n$ , then  $W > \bar{W}$  and  $W > \hat{W}$ . If  $W^s < W^n$ , then  $W < \bar{W}$ .

Proposition 2 provides support for the notion that, even in terms of social welfare, sophisticated agents tend to be disproportionately important. That is, given a few restrictions, the following two statements are necessarily true. First, in response to the behavior of the naive, the sophisticated react in a manner which drives social welfare towards  $W^s$  and away from  $W^n$ . Second, for the case  $W^s > W^n$ , it is also true that  $W$  is closer to  $W^s$  than would be suggested by the relative number of sophisticated agents and naive agents in the population. The reason our results are stronger for the case  $W^s > W^n$  is the following. As indicated above, given our restrictions we are able to demonstrate that the response of the sophisticated to the behavior of the naive always drives social welfare towards  $W^s$  and away from  $W^n$ . It is also true that, given our restrictions,  $\hat{W}$  is never less than  $\bar{W}$ . Thus, when  $W^s > W^n$ ,  $W > \hat{W}$  implies  $W > \bar{W}$ . However, when  $W^s < W^n$  the same logic does not apply.

A word is in order concerning our restrictions. First, we assume there are increasing marginal congestion effects, that is,  $f_A'' \leq 0$  and  $f_B'' \leq 0$ . This assumption basically serves to guarantee that social welfare is a single-peaked function of the number of sophisticated agents who take each path—a property which is critical for our proof.<sup>10</sup> Second, we assume that either  $N_A^s, N_A^n \leq N_A^0$  or  $N_A^s, N_A^n \geq N_A^0$ . The role of this assumption is as follows. Our proof relies on the idea that, when the behavior of the naive drives social welfare down, the sophisticated respond by shifting towards first-best optimal behavior—thus driving social welfare up. On the other hand, when the behavior of the naive drives social welfare up, the sophisticated respond by shifting away from first-best optimal behavior—thus driving social welfare down. The role of the restriction that either  $N_A^s, N_A^n \leq N_A^0$  or  $N_A^s, N_A^n \geq N_A^0$  is primarily to guarantee that the response of the sophisticated, relative to first-best optimal behavior,

<sup>10</sup> There is evidence, however, that suggests that, at least for our transportation interpretation, it is reasonable to assume increasing marginal congestion effects (see Theodore Keeler and Kenneth Small, 1977).

is consistent with the above. For example, suppose the restriction was violated and the naive behaved in a manner that tended to lower social welfare. Even though the sophisticated would respond by having behavior being biased in an exactly opposite manner, given that our restriction is violated, this could actually entail having the behavior of the sophisticated move away from first-best optimal behavior.<sup>11</sup>

One interesting implication of Proposition 2 concerns the following issue. Consider a choice situation where a proportion of the population is naive, and the naive behave in a manner that lowers social welfare. Proposition 2 tells us that, if the environment exhibits congestion effects, then there may be little reason to be concerned about the incorrect expectations of the naive. That is because, in response to the behavior of the naive, the sophisticated tend to react in a manner which reduces the social welfare loss attributable to these incorrect expectations.

Finally, we would like to point out that in addition to providing insights concerning the interaction of naive and sophisticated agents, this model can also be used to provide insights concerning the interaction of informed and uninformed agents (see Sanford Grossman and Joseph Stiglitz, 1980, and Russell Cooper and Thomas Ross, 1984). That is, the model can be reinterpreted as one where all agents have rational expectations, but only some agents are informed about a relevant piece of information. For example, consider

the problem of commuters having to choose which of two routes to travel, where only some agents are aware that one of the routes has a lane blocked off. The model analyzed in this section can be reinterpreted as a model of just this problem. Under this interpretation the sophisticated agents become the agents who are informed of the closed lane, while the naive agents become the uninformed agents. The conclusion that can be drawn concerning the interaction of informed and uninformed agents is basically the same conclusion as drawn above for sophisticated and naive agents. That is, when there are congestion effects, informed agents tend to have a disproportionately large effect on equilibrium.

## II. Choosing Paths with Synergistic Effects

Here we consider the problem of agents choosing between two paths, where the paths exhibit synergistic effects. By synergistic effects we mean that for any agent  $i$ , the higher is the number of other agents who choose the same path as the one chosen by agent  $i$ , the better off is agent  $i$ . An example of a real world choice situation that exhibits synergistic effects is the problem faced by consumers in choosing a computer hardware system. This choice problem exhibits synergistic effects in that the larger the number of individuals who purchase a particular system, the greater will be the subsequent availability of computer peripherals and software for that system. Other examples include the problems faced by consumers in choosing between a cassette and an 8-track tape player, and the choice between the Beta and VHS formats for video cassette recorders. Similar to the computer example, these choice problems exhibit synergistic effects because the larger the number of individuals who purchase a particular system, the greater will be the subsequent variety of tapes available for that system.

To investigate the problem of agents choosing between paths when synergistic effects are present, we analyze a variant of the model developed in the previous section. The new assumptions are as follows. First we assume  $f'_A \geq 0$ ,  $f'_B \geq 0$  and that one of the

<sup>11</sup>An additional reason for imposing the restriction that either  $N_A^s, N_A^n \leq N_A^O$  or  $N_A^s, N_A^n \geq N_A^O$  is that without the restriction some of the comparisons we make in Proposition 2 can be quite misleading. Consider, for example, the following discussion concerning  $\hat{W}$ . When the restriction that either  $N_A^s, N_A^n \leq N_A^O$  or  $N_A^s, N_A^n \geq N_A^O$  is satisfied,  $\hat{W}$  will necessarily lie strictly between  $W^s$  and  $W^n$ . Thus, if the restriction is satisfied, our comparison will suggest that the sophisticated are disproportionately important whenever the response of the sophisticated moves social welfare towards  $W^s$ . When the restriction is not satisfied, however,  $\hat{W}$  can actually lie outside the interval defined by  $W^n$  and  $W^s$ . Thus, if the restriction were not satisfied, our comparison could actually suggest that the naive are disproportionately important even when it is the case that  $W = W^s$ .

two is everywhere strictly positive. Second,  $[f'_A(\int_0^z g(c_i)dc_i) + f'_B(\int_z^C g(c_i)dc_i)]g(z)/2 < 1$  for all  $0 \leq z \leq C$  is assumed. The first assumption insures that the model now exhibits synergistic effects; the second assumption eliminates the possibility of multiple equilibria (note: in Section I no similar assumption was needed to rule out the possibility of multiple equilibria).

Under this specification equations (1)–(4) of the previous section continue to hold. We now proceed to the Section II analogue of Proposition 1.

**PROPOSITION 3:** *If  $0 < p < 1$  and  $N_A^n \geq N_A^s$ , then  $N_A = pN_A^s + (1-p)N_A^n$ . Note, this also implies that if  $0 < p < 1$  and  $N_B^n \geq N_B^s$ , then  $N_B = pN_B^s + (1-p)N_B^n$ .*

The interpretation of Proposition 3 is straightforward. When agents choose among paths which exhibit synergistic effects, naive agents, rather than sophisticated agents, have a disproportionately large effect on the number of agents who take each path. That is, in terms of the number of agents who take each path, the equilibrium more closely resembles the pure limited rationality equilibrium than would be suggested by the relative number of sophisticated agents and naive agents in the population.

We feel this result is especially interesting in that it provides a rationale for the persistent dominance of IBM in the computer industry. As mentioned earlier, one example of a choice situation that exhibits synergistic effects is the problem of choosing a computer hardware system. This problem exhibits synergistic effects because the availability of computer peripherals and software for a system depends on the number of individuals who purchase the system. Now, suppose each time a new generation of computers comes onto the market, a segment of the population anticipates that the market shares of the different brands will be the same as for the previous generation of computers. Because of the synergistic properties of the market, in such a situation brands that are successful in one period would have a high probability of having their success repeated. There are two reasons for this. First, consumers who extrapolate will tend to

purchase brands with previous high market shares. Second, given Proposition 3, it is also true that more sophisticated consumers will tend to behave in this manner. Thus, the persistent dominance of IBM in the computer industry may very well be due to the synergistic properties of the market.

The next step of the analysis is to consider again the social welfare aspects of the model. In what ensues  $W$ ,  $\bar{W}$ ,  $\hat{W}$ ,  $N_A^O$  and  $N_B^O$  will be defined as in Section I. For the analysis of synergistic effects, however, it is also necessary to define some terms concerning the following second-best problem. Suppose there was a social welfare-maximizing government which was all knowing, but which could only direct the actions of the sophisticated agents in the population. We denote as  $N_A^O(N_B^O)$  the total number of agents who would wind up at path  $A(B)$ , given a government with this limited ability to direct behavior.

We can now make comparisons between  $W$  and our two social welfare benchmarks.

**PROPOSITION 4:** *Suppose  $f_A'' \leq 0$ ,  $f_B'' \leq 0$ ,  $0 < p < 1$  and that either  $N_A^s, N_A^n \leq N_A^O$  and  $\hat{N}_A \leq N_A^O$ , or  $N_A^s, N_A^n \geq N_A^O$  and  $\hat{N}_A \geq N_A^O$ , where  $\hat{N}_A = pN_A^s + (1-p)N_A^n$ . If  $W^n < W^s$ , then  $W < \bar{W}$  and  $W < \hat{W}$ . If  $W^n > W^s$ , then  $W > \bar{W}$ .*

Proposition 4 provides support for the notion that, even in terms of social welfare, naive agents tend to be disproportionately important. That is, given a few restrictions, the following two statements are necessarily true. First, in response to the behavior of the naive, the sophisticated react in a manner which drives social welfare towards  $W^n$  and away from  $W^s$ . Second, if  $W^n > W^s$ , then  $W$  is closer to  $W^n$  than would be suggested by the relative number of sophisticated agents and naive agents in the population. The reason our results are stronger for the case  $W^n < W^s$  is similar to the reason our results in Proposition 2 were stronger for the case  $W^n < W^s$ . The only difference is that now  $\bar{W}$  is never less than  $\hat{W}$ .

A word is in order concerning our restrictions. First, we assume there are decreasing marginal synergistic effects, that is,  $f_A'' \leq 0$  and  $f_B'' \leq 0$ . As was the role of the assump-

tion of increasing marginal congestion effects in Proposition 2, this assumption guarantees that social welfare is a single-peaked function of the number of sophisticated agents who take each path. Second, we assume that either  $N_A^s, N_A^n \leq N_A^o$  and  $\hat{N}_A \leq N_A^o$ , or  $N_A^s, N_A^n \geq N_A^o$  and  $\hat{N}_A \geq N_A^o$ . This assumption serves the same role as the assumption in Proposition 2 that either  $N_A^s, N_A^n \leq N_A^o$  or  $N_A^s, N_A^n \geq N_A^o$ . One question that arises is, why is the condition more restrictive in Proposition 3? The answer is that, when there are congestion effects (assuming that  $N_A^s, N_A^n \leq (\geq) N_A^o$  guarantees that  $\hat{N}_A \leq (\geq) N_A^o$ ). A second question is, what is the role played by the additional restriction? Propositions 2 and 3 work because, under our restrictions, the following statement is satisfied. When the presence of naive agents causes the behavior of the sophisticated to move away from (towards) first-best optimal behavior, social welfare tends to be driven down (up) or below (above) our social welfare benchmarks. The role of our additional restriction is simply to guarantee that the above statement is valid. That is, if the restriction is violated, then we have the possibility of a standard second-best problem wherein having the sophisticated move away from (towards) first-best optimal behavior might actually increase (decrease) social welfare.

As in the previous section, we can consider what our analysis implies for a choice situation where a proportion of the population is naive, and the naive behave in a manner that tends to lower social welfare. Proposition 4 tells us that, if such a choice environment exhibits synergistic effects, then there may be reason to be quite concerned about the incorrect expectations of the naive. That is because, in response to the behavior of the naive, the sophisticated now react in a manner that tends to increase the social welfare loss attributable to these incorrect expectations.

Finally, in concluding the previous section we noted that in addition to providing insights concerning the interaction of naive and sophisticated agents, the model of Sections I and II can also be used to provide insights concerning the interaction of informed and uninformed agents. That is, the model can be reinterpreted as one where all

agents have rational expectations, but only some agents are informed of a relevant piece of information. Our conclusion regarding this point in Section I was that, when there are congestion effects, informed agents tend to have a disproportionately large effect on equilibrium. In contrast, the conclusion we can draw from the analysis of Section II is that, when there are synergistic effects, the uninformed agents tend to be the ones who are disproportionately important.

### III. The Chain-Store Paradox Revisited

Here we analyze a variant of a game initially studied by Selten. The game is basically described as follows. Let there be a monopolist who operates in  $T$  separate markets, and who sequentially faces a different potential entrant in each market. Furthermore, in each market let the potential entrant move first by deciding whether or not to enter the market. If the potential entrant decides not to enter, then there are no further moves by players in that market. If entry does occur, however, then the monopolist has to decide whether to cooperate or to act aggressively. Finally, let payoffs satisfy the following three conditions. First, if entry has occurred in market  $k$ , then both the monopolist and the entrant receive higher profits in market  $k$  if the monopolist acts cooperatively. Second, for each market  $k$ , the monopolist receives even higher profits if entry does not occur. Third, for each market  $k$ , if the monopolist is sure to act aggressively then the potential entrant is better off not entering.

Selten referred to this game as the chain-store game, and pointed out that the game embodies a paradox. On the one hand, intuition suggests that if such a game were to actually be played, the monopolist would likely act aggressively whenever entry occurs in an early market, and in turn this would limit the number of markets in which entry occurs. On the other hand, game theory predicts that entry will occur in every market, and that the monopolist will cooperate each time entry occurs.

Recently, Kreps-Wilson and Milgrom-Roberts have demonstrated one way in which the paradox can be resolved. Their basic idea

is that, if there is even a small probability that the monopolist always acts aggressively, then the resulting equilibrium closely resembles the intuitive equilibrium specified above. That is, the monopolist always acts aggressively if entry occurs in an early market, and this in turn deters entry in early markets.<sup>12</sup>

In this section we investigate what happens when the decision-making process of the potential entrants is varied, rather than the above approach of varying the decision-making process of the monopolist. Specifically, we investigate how equilibrium is affected when, for each market, there is some probability that the potential entrant is naive and forms expectations by simply extrapolating from previous behavior. The basic result that emerges from our analysis is that, when reputation effects are potentially important, it is possible for either type of agent to be dominant. That is, under some parameterizations, sophisticated agents will have a disproportionately large effect on equilibrium, while for other parameterizations, the naive agents will be the ones who are disproportionately important.

As stated previously, we consider a monopolist who operates in  $T$  separate markets, and who faces a different potential entrant in each market. It is assumed that the monopolist and the potential entrants are all risk neutral, and that the monopolist faces the  $T$  potential entrants in a sequential fashion. By the latter we mean that the monopolist first faces the potential entrant in what we refer to as market 1, and then sequentially faces the potential entrants in markets 2, 3...  $T$ . In each market, furthermore, payoffs to the players are as in Figure 1. Note, we consider the case  $0 < b < 1$  and  $a > 1$ . Also, it is assumed that when the potential entrant in each market  $k$  faces the monopolist, the potential entrant is aware of all moves by players in lower-numbered markets.

To complete the model, we must specify the manner in which players form expectations. With probability one, the monopolist

		PAYOFFS	
		ENTRANT'S	MONOPOLIST'S
ENTRANT STAYS OUT	MONOPOLIST ACQUIESCES	0	$a$
	MONOPOLIST FIGHTS	$b$	0
ENTRANT ENTERS		$b-1$	-1

FIGURE 1

is sophisticated and thus has rational expectations. On the other hand, for each market  $k$  there is a probability  $p$  that the potential entrant is sophisticated, and a probability  $(1-p)$  that the potential entrant is naive. If a potential entrant is sophisticated, then he also has rational expectations. If a potential entrant is naive, then he simply extrapolates from previous behavior. Specifically, if the last entry brought forth a cooperative (aggressive) response from the monopolist, then a naive potential entrant anticipates that with probability one a further entry will bring forth a cooperative (aggressive) response.<sup>13</sup> If there are no prior entries to extrapolate from, however, then a naive potential entrant anticipates that, with probability  $\pi$ , entry is met by cooperation and with probability  $(1-\pi)$  entry is met by aggression. Finally, to keep the analysis simple we place the following two restrictions on the parameters. First,  $\pi b + (1-\pi)(b-1) < 0$ , that is, a naive potential entrant does not enter if there are no prior entries to extrapolate from.<sup>14</sup> Second, for every integer  $k$  in the interval  $[1, T-1]$  it is the case that  $\sum_{i=1}^k (1-p)^i a \neq 1$ .

The following four propositions characterize perfect Nash equilibria for our model as a function of the exogenous parameters. By restricting the analysis to perfect Nash equilibria, we eliminate the possibility that sophisticated players maintain threats which they would not find rational to carry out (see Selten for a discussion of perfectness in this context).

<sup>13</sup>This type of oversensitivity by agents to the most recent information available is consistent with empirical evidence (see Arrow), and with the work of cognitive psychologists (see Kahneman et al.).

<sup>14</sup>This assumption is not critical, but rather as mentioned above serves to simplify the analysis. In our paper (1983), we indicate the results that follow from the alternative that  $\pi b + (1-\pi)(b-1) > 0$ .

<sup>12</sup>The description of Milgrom and Roberts above is somewhat imprecise. They actually show that the paradox can be resolved by having the potential entrants only perceive that there is a probability that the monopolist always acts aggressively.

**PROPOSITION 5:** *If  $p=1$  then (i) entry occurs in every market and (ii) the monopolist cooperates every time entry occurs.*

Proposition 5 tells us that in the absence of any limited rationality our model yields Selten's chain-store paradox. That is, when with probability one each potential entrant is sophisticated, entry occurs in each market and the monopolist cooperates each time entry occurs. We now analyze the other polar case.

**PROPOSITION 6:** *If  $p=0$ , then entry never occurs.*

Proposition 6 indicates that, when with probability one each potential entrant is naive, the model yields results exactly opposite from those that held when with probability one each potential entrant was sophisticated. Note, the proof of Proposition 6 depends on the assumption  $\pi b + (1-\pi)(b-1) < 0$ . However, the equilibrium would only change slightly with the opposite assumption. Specifically, if  $\pi b + (1-\pi)(b-1) > 0$ , equilibrium is characterized by the following three statements. First, the period 1 potential entrant would enter. Second, the monopolist would respond by acting aggressively. Third, entry would not occur in any other market.

We have now analyzed the two polar cases of pure rational expectations and pure limited rationality. Our next two propositions consider restrictions on the parameter space which are between these two polar cases.

**PROPOSITION 7:** *If  $\sum_{i=1}^{T-1}(1-p)^i a < 1$ , then (i) entry first occurs in the lowest-numbered market that contains a sophisticated potential entrant, (ii) entry occurs in every succeeding or higher-numbered market, and (iii) the monopolist cooperates each time entry occurs.*

Propositions 5 and 6 indicate that, for neither type of agent to be disproportionately important, entry should occur on average in  $pT$  markets. However, Proposition 7 indicates that when  $\sum_{i=1}^{T-1}(1-p)^i a < 1$ , entry occurs on average in  $\sum_{i=1}^{T-1}(1-(1-p)^i)$  markets, and it is easily shown that  $\sum_{i=1}^{T-1}(1-(1-p)^i)$  always exceeds  $pT$  and, in

fact, it frequently exceeds  $pT$  by a wide margin. For example, if  $T=10$  and  $p=1/2$ , then  $pT=5$  and  $\sum_{i=1}^9(1-(1-p)^i) \approx 9$ . Thus, for the parameterizations covered by Proposition 7, sophisticated agents are disproportionately important.

**PROPOSITION 8:** *If  $\sum_{i=1}^{T-1}(1-p)^i a > 1$ , then (i) entry does not occur in markets 1 through  $T-z$ , where  $z$  is the lowest integer for which  $\sum_{i=1}^z(1-p)^i a > 1$ , (ii) for markets numbered above  $T-z$ : (a) entry first occurs in the lowest-numbered market that contains a sophisticated potential entrant, (b) entry occurs in every succeeding or higher-numbered market, and (c) the monopolist cooperates each time entry occurs.*

As stated previously, Propositions 5 and 6 indicate that, for neither type of agent to be disproportionately important, entry should occur on average in  $pT$  markets. However, Proposition 8 tells us that, for some parameterizations, entry occurs on average in less than  $pT$  markets. For example, if  $(1-p)a > 1$ , then entry occurs on average in  $p$  markets, and  $p$  is obviously less than  $pT$ . Thus, Proposition 8 indicates that there are some parameterizations for which naive potential entrants have a disproportionately large effect on equilibrium.

Proposition 8 concludes our analysis of the chain-store paradox. In summary, we have found that, in a repeating-game situation where reputation is a potential factor, it is possible for either type of agent to dominate. That is, for some parameterizations sophisticated agents will have a disproportionately large effect on equilibrium, while for other parameterizations the naive agents will be the ones with the disproportionately large effect.

Finally, given that either type of agent can dominate, a question arises as to which type of agent will in general dominate in such repeated-game situations. Although it is difficult to quantify, we feel that, at least for chain-store-like games, the naive agents will in general be the dominant ones. There are two pieces of evidence that point in this direction. First, one interpretation of the Kreps-Wilson and Milgrom-Roberts results is that, when the probability for limited ra-

tionality is introduced on the side of the monopolist, then it is almost always the probability of naiveté that is disproportionately important. Second, in a richer version of the model analyzed in this section, the restriction needed for the naive agents to be dominant becomes much less stringent. Specifically, consider a model where there is some uncertainty concerning what the monopolist receives in a market when entry does not occur. Preliminary analysis suggests that as long as there is some probability that  $(1 - p)$  times this return is greater than one, the naive agents will be the ones who dominate.

#### IV. Conclusion

Papers that provide alternatives to the rationality assumption, as well as papers that contain the rationality assumption, have in general ignored the idea that agents tend to vary in terms of information processing abilities. Here we have attempted to investigate the ramifications of this type of heterogeneity. We did this by analyzing two simple models in which the population is composed of two groups. Agents in the first group were characterized by rational expectations and were referred to as sophisticated, while agents in the second group were characterized by incorrect expectations and were referred to as naive. The analysis yielded three major results. First, in a world characterized by congestion effects, sophisticated agents tend to have a disproportionately large effect on equilibrium. Second, in a world characterized by synergistic effects, naive agents tend to be disproportionately important. Third, in a repeating-game situation where reputation is a potential factor, it is possible for either type of agent to be dominant. Finally, the analysis also yielded insights concerning the interaction of informed and uninformed agents, where all agents have rational expectations. Specifically, the analysis suggests that, for situations which exhibit congestion effects, informed agents tend to have a disproportionately large effect on equilibrium. On the other hand, for situations that exhibit synergistic effects, the analysis suggests that uninformed agents are the ones who are disproportionately important.

The research presented in this paper could be extended in a number of directions. One direction of particular interest concerns the applicability of the results contained herein to the rational expectations challenge to Keynesian macroeconomics. This challenge has left macroeconomics in a state of flux. The reason being that, although the challenge has brought to the fore the theoretical inconsistencies inherent in Keynesian macroeconomics, simple rational expectations macroeconomic models do not yield predictions consistent with empirical observation. The profession has responded to this situation by embedding a variety of imperfections and rigidities into rational expectations models (for example, staggered long-term contracts are introduced in John Taylor, 1980, lags in the production process are introduced in Finn Kydland and Edward Prescott, 1982, and uncertainty with Bayesian learning is introduced in Roman Frydman and Edmund Phelps, 1983). The analysis in this paper suggests a different response. That is, rather than assuming rational expectations and then introducing imperfections, why not start with the more realistic assumption that agents are heterogeneous in terms of their information-processing abilities. We feel such an approach shows particular promise because of the following. First, given the similarity between our description of synergistic interaction among agents and old style Keynesian multiplier analysis, it would not be surprising if macroeconomic models with this type of heterogeneity exhibited synergistic effects. Second, our results suggest that if this is indeed the case, then it may very well be that the naive agents are the ones who would be dominant in such a model.<sup>15</sup>

#### APPENDIX

More detailed proofs of many of the propositions are contained in our earlier paper.

<sup>15</sup> See Akerlof and Yellen for macroeconomic examples wherein the presence of naive agents has a critical effect on the nature of equilibrium. Note, however, their results are not driven by the presence of either congestion or synergistic effects.

## PROOF of Proposition 1:

Suppose not, that is, suppose for instance that  $N_A^s > N_A^n$  and that there exists a  $0 < p < 1$ , denoted  $\hat{p}$ , such that  $N_A \leq \hat{p}N_A^s + (1 - \hat{p})N_A^n$ . Our suppositions that  $N_A^s > N_A^n$  and  $N_A \leq \hat{p}N_A^s + (1 - \hat{p})N_A^n$  together with the definitions of  $D$  and  $D^s$  yield that  $D$  at  $p = \hat{p}$  must exceed  $D^s$ . On the other hand, our two suppositions together with (3) and the definitions of  $D^n$ ,  $N_A^s$  and  $N_A^n$  yield that  $D^s$  must exceed or equal  $D$  at  $p = \hat{p}$ . Thus we have a contradiction, which means that if  $0 < p < 1$  and  $N_A^s > N_A^n$ , then  $N_A > pN_A^s + (1 - p)N_A^n$ . The other cases are demonstrated similarly.

## PROOF of Proposition 2:

Note, first, all the restrictions in the statement of the proposition are being assumed throughout the proof. We know that

$$(A1) \quad W = p \left[ \int_0^D (f_A(N_A) - c_i) g(c_i) dc_i + \int_D^C (f_B(N_B) - (C - c_i)) g(c_i) dc_i \right] + (1 - p) \left[ \int_0^{D^n} (f_A(N_A) - c_i) g(c_i) dc_i + \int_{D^n}^C (f_B(N_B) - (C - c_i)) g(c_i) dc_i \right].$$

Note,  $W = W^s$  when  $p = 1$ ,  $W = W^n$  when  $p = 0$ , and  $W = \hat{W}$  when  $D = D^s$ ,  $N_A = \hat{N}_A$  and  $N_B = \hat{N}_B$ , where  $\hat{N}_A = \int_0^{D^s} p g(c_i) dc_i + \int_0^{D^n} (1 - p) g(c_i) dc_i$  and  $\hat{N}_B = \int_{D^s}^C p g(c_i) dc_i + \int_{D^n}^C (1 - p) g(c_i) dc_i$ .

Consider a social welfare-maximizing government that could direct the actions of all the agents in the population. Such a government would choose  $D^*$  to maximize

$$(A2) \quad W^* = \int_0^{D^*} (f_A(N_A^*) - c_i) g(c_i) dc_i + \int_{D^*}^C (f_B(N_B^*) - (C - c_i)) g(c_i) dc_i,$$

where  $N_A^* = \int_0^{D^*} g(c_i) dc_i$

and  $N_B^* = \int_{D^*}^C g(c_i) dc_i$ .

Differentiation yields that  $W^*$  is a single-peaked function of  $D^*$ , that is,  $(\partial W^* / \partial D^*)$

$> 0$  for  $D^* < D^0$  and  $(\partial W^* / \partial D^*) < 0$  for  $D^* > D^0$ , where  $D^0 = \arg \max_{D^*} W^*$ .

Now consider a social welfare-maximizing government which could only direct the actions of the sophisticated agents in the population. Such a government would choose  $D^+$  to maximize

(A3)

$$W^+ = (1 - p) \left[ \int_0^{D^n} (f_A(N_A^+) - c_i) g(c_i) dc_i + \int_{D^n}^C (f_B(N_B^+) - (C - c_i)) g(c_i) dc_i \right] + p \left[ \int_0^{D^+} (f_A(N_A^+) - c_i) g(c_i) dc_i + \int_{D^+}^C (f_B(N_B^+) - (C - c_i)) g(c_i) dc_i \right],$$

where  $N_A^+ = \int_0^{D^n} (1 - p) g(c_i) dc_i + \int_0^{D^+} p g(c_i) dc_i$  and  $N_B^+ = \int_{D^n}^C (1 - p) g(c_i) dc_i + \int_{D^+}^C p g(c_i) dc_i$ . Differentiation yields that  $W^+$  is a single-peaked function of  $D^+$ . Denote  $N_A^o(N_B^o)$  as the number of agents who would wind up at path  $A(B)$ , given a government with this limited ability to direct behavior.

Suppose  $W^n < W^s$  and  $N_A^s > N_A^n$ . Given the single-peaked property of  $W^*$ , this implies  $N_A^n < N_A^s \leq N_A^o$ . Given Proposition 1, this in turn implies  $N_A > \hat{N}_A$ . It can be demonstrated that  $N_A^n, N_A^s < \hat{N}_A^o$  implies  $N_A < N_A^o$ .<sup>16</sup> Hence, we have  $N_A^o > N_A > \hat{N}_A$ . Given the single-peaked property of  $W^+$ , this in turn implies that if  $W^n < W^s$  and  $N_A^s > N_A^n$ , then  $W > \hat{W}$ . Moreover, given the symmetry of the problem, this result yields that  $W^n < W^s$  and  $N_A^s < N_A^n$  imply  $W > \hat{W}$ .

The assumptions  $f_A'' \leq 0$  and  $f_B'' \leq 0$  yield  $\hat{W} > \bar{W}$ . Given the preceding result, this in turn yields that  $W^s > W^n$  implies  $W > \bar{W}$ .

Finally, the proof that  $W^n > W^s$  implies  $W < \hat{W}$  follows along similar lines.

## PROOF of Proposition 3:

Suppose not, that is, suppose for instance that  $N_A^n < N_A^s$  and that there exists a  $0 < p <$

<sup>16</sup>See the mathematical supplement mentioned in fn. 7.

1, denoted  $\hat{p}$ , such that  $N_A \geq \hat{p}N_A^s + (1 - \hat{p})N_A^n$ . Given this, (3), and the definitions of  $N_A^n$  and  $N_A^s$  yield that  $D$  at  $p = \hat{p}$  must exceed or equal  $D^s$ . On the other hand, our assumption  $[f'_A(\int_0^z g(c_i)dc_i) + f'_B(\int_z^1 g(c_i)dc_i)]g(z)/2 < 1$  for all  $0 \leq z \leq C$  combined with (3) yields that  $N_A$  is a strictly increasing function of  $N_A^n$ . We also know  $N_A = N_A^s$  when  $N_A^n = N_A^s$ , which given the preceding implies  $N_A$  at  $p = \hat{p}$  must be strictly less than  $N_A^s$ . Furthermore, given  $f'_A \geq 0$ ,  $f'_B \geq 0$  and that one is always strictly positive, the fact that  $N_A^s$  exceeds  $N_A$  at  $p = \hat{p}$  yields a contradiction because it implies  $D^s$  exceeds  $D$  at  $p = \hat{p}$ . Thus, when  $N_A^n < N_A^s$ , it must be the case that  $N_A < pN_A^s + (1 - p)N_A^n$ . The other cases are demonstrated similarly.<sup>17</sup>

#### PROOF of Proposition 4:

Note, first, all the restrictions in the statement of the proof are assumed throughout the proof. Given these restrictions,  $W^*$  remains a single-peaked function of  $D^*$  and  $W^+$  a single-peaked function of  $D^+$ .

Suppose  $W^n < W^s$  and  $N_A^s > N_A^n$ . Given the single-peaked property of  $W^*$ , this implies  $N_A^n < N_A^s \leq N_A^0$ . In turn, given Proposition 3 and the single-peaked property of  $W^+$ , this yields that when  $W^n < W^s$  and  $N_A^s > N_A^n$ , then  $W < \hat{W}$ . Moreover, because of the symmetry of the problem, this result yields that  $W^n < W^s$  and  $N_A^n > N_A^s$  imply  $W < \hat{W}$ .

From the definitions, it is necessarily true that  $\hat{W} - \bar{W} = 0$  when  $N_A^s = N_A^n$ . It is also true that  $\partial(\hat{W} - \bar{W})/\partial N_A^n \geq 0$  when  $N_A^n \leq N_A^s$ . Together these two statements imply  $\hat{W} < \bar{W}$  when  $N_A^s \neq N_A^n$ . This, combined with

the preceding result, in turn, yields that  $W^s > W^n$  implies  $W < \bar{W}$ .

Finally, the proof that  $W^n > W^s$  implies  $W > \bar{W}$  follows along similar lines.

#### PROOF of Proposition 5:

Consider first market  $T$ . If entry occurs the only rational response for the monopolist is to cooperate. Given this, the only rational move for the market  $T$  potential entrant is to enter. Now consider market  $k$ , where it is known that entry will necessarily occur in every higher-numbered market. If entry occurs in market  $k$ , given that entry is going to occur in every higher-numbered market, the only rational response for the monopolist is to cooperate. This in turn yields that the only rational move for the market  $k$  potential entrant is to enter. Finally, the above two ideas yield that the only perfect Nash equilibrium is for entry to occur in every market, and for the monopolist to cooperate every time entry occurs.

#### PROOF of Proposition 6:

This follows immediately from our assumption  $\pi b + (1 - \pi)(b - 1) < 0$ .

#### PROOF of Proposition 7:

Consider market  $T$ . If entry occurs, the only rational response for the monopolist is to cooperate. Given this, the market  $T$  potential entrant will enter if he is sophisticated. Now consider market  $T - 1$ . Given the above and the fact that  $(1 - p)a < 1$ , the only rational response for the monopolist is again to cooperate. This in turn yields that the market  $T - 1$  potential entrant will enter if he is sophisticated. Furthermore, successively repeating this argument yields that entry will occur in each market that contains a sophisticated potential entrant, and the monopolist will cooperate every time entry occurs.

To complete the proof we need only demonstrate that a naive potential entrant will (will not) enter if there is (is not) a lower-numbered market that contains a sophisticated potential entrant. Consider first a naive potential entrant for whom there is a lower-numbered market that contains a sophisticated potential entrant. For this

<sup>17</sup>One point that should be noted is that this proof relies heavily on the assumption employed to eliminate the possibility of multiple equilibria. We conjecture that, without this assumption, there would always be equilibria consistent with the proposition. On the other hand, without the assumption, it would probably also be possible to have equilibria that were inconsistent with the proposition. What this suggests to us is that, when there are synergistic effects, it is possible for sophisticated agents to dominate. However, this would only occur when, in a sense, the presence of naive agents caused the economy to jump between different families of equilibria.

potential entrant, extrapolation yields that the monopolist cooperates, and thus such a potential entrant will enter. Now consider a naive potential entrant for whom there is no lower-numbered market that contains a sophisticated potential entrant. For this potential entrant, there will be no prior entries to extrapolate from, and thus such a potential entrant will not enter.

#### PROOF of Proposition 8:

Suppose (i) is true. Given this, (ii) follows from the same logic as in the proof of Proposition 7. Thus, we need only prove (i).

Consider a sophisticated potential entrant located in a market  $k$ , where  $1 \leq k \leq T - z$ . If this potential entrant were to enter, the monopolist would act aggressively because the expected return from the deterrence of future naive potential entrants would exceed the immediate return to cooperating, that is,  $\sum_{i=1}^{T-k} (1-p)^i a > 1$ . Thus, the only rational move for such a sophisticated potential entrant would be not to enter. Furthermore, given this, it follows immediately that any naive potential entrant located in a market  $k$ , where  $1 \leq k \leq T - z$ , would also decide not to enter.

# Do Markets Differ Much?

By RICHARD SCHMALENSEE\*

This essay reports the results of a cross-section study of differences in accounting profitability that sheds light on some basic controversies in industrial economics. Most previous cross-section studies in this field have been concerned with testing hypotheses about structural coefficients in models meant to apply to essentially all markets. As we have learned more about the difficulties of constructing such general models and of performing tests on their structural parameters properly, structural cross-section analysis has fallen out of fashion. In contrast to most of the cross-section literature, the analysis reported here is fundamentally descriptive; it does not attempt directly to estimate or to test hypotheses about structural parameters.

I hope to show by example that one can perform illuminating analysis of cross-section data without a host of controversial maintained hypotheses. Cross-section data can yield interesting stylized facts to guide both general theorizing and empirical analysis of specific industries, even if they cannot

easily support full-blown structural estimation.<sup>1</sup> One can view the sort of search for stylized facts conducted here as either a replacement for or an input to interindustry structural estimation, depending on one's feeling about the long-run potential of that research approach. This study also departs from much of the cross-section literature by being fundamentally concerned with the *importance* of various effects, not just with coefficient signs and *t*-statistics.

In particular, this essay provides estimates of the relative importance of firm, market, and market share differences in the determination of business unit (divisional) profitability in U.S. manufacturing. Using 1975 data from the Line of Business Program of the U.S. Federal Trade Commission (FTC), I find support neither for the *existence* of firm effects nor for the *importance* of market share effects. Moreover, while industry effects apparently exist and are important, they appear to be *negatively* correlated with seller concentration in these data.

Section I relates firm, market, and share effects to current issues and controversies in industrial economics and thus supplies the motivation for our empirical analysis. The remainder of the essay treats the data and statistical methods employed (Section II), the empirical results obtained (Section III), and the main implications of those results (Section IV).

## I. Sources of Profitability Differences

In the *classical* tradition, following Joe Bain (1951, 1956), industrial economists treated the industry or market as *the* unit of

\*Sloan School of Management, Massachusetts Institute of Technology, Cambridge, MA 02139. I am indebted to Stephen Postrel for excellent research assistance, to the FTC's Line of Business staff, particularly David Lean, William Long, and David Ravenscraft, for a variety of indispensable inputs, and to Ian Ayres, Richard Caves, Jerry Hausman, Paul Joskow, John Scott, anonymous referees, and, especially, Thomas Stoker for valuable advice. Seminar audiences at Stanford, Berkeley, Chicago, Northwestern, and British Columbia provided useful comments on earlier versions of this essay. Finally, I am grateful for financial support from the National Science Foundation, the U.S. Federal Trade Commission, and the Ford Motor Company (through a grant to MIT). The representations and conclusions presented herein are my own and have not been adopted in whole or in part by the FTC or its Bureau of Economics. The Manager of the Line of Business Program has certified that he has reviewed and approved the disclosure avoidance procedures used by the staff of the Line of Business Program to ensure that the data included in this paper do not identify individual company Line of Business data. I alone can be held responsible for this paper's contents.

<sup>1</sup>Christopher Sims (1980) has expressed a similar methodological position in the context of macroeconomics. The approach taken by Michael Gort and Rao Singamsetti (1976) is close in some respects to that taken here. They use firm-level data, however, and obtain very different results.

study. Differences among firms were assumed transitory or unimportant unless based on scale economies, which were generally found to be insubstantial. Equilibrium industry profitability was generally assumed to be primarily determined by the ability of established firms to restrict rivalry among themselves and the protection afforded them by barriers to entry. A central hypothesis in virtually all the classical work was that increases in seller concentration tend to raise industrywide profits by facilitating collusion. Most classical studies thus included concentration among the independent variables in regression analysis of industry average rates of return, and most published studies reported the coefficient of concentration to be positive and significant.<sup>2</sup>

An anticlassical, *revisionist* view of industrial economics has emerged in the last decade. In the simplest model consistent with this view, all markets are (at least approximately) competitive, and scale economies are absent (or negligible). The key assumption is that within at least some industries there are persistent efficiency differences among sellers.<sup>3</sup> Because more efficient enterprises tend both to grow at the expense of their rivals and to be more profitable, these differences tend to induce a positive intra-industry correlation between share and profitability even in the absence of scale economies. Moreover, the more important are efficiency differences in any industry, the less equal are market shares (and thus the higher is market concentration) and the higher are the profits of the leading firms (and thus the higher is industry average profitability). This model

thus predicts a positive correlation between concentration and profitability in cross section at the industry level even though, by assumption, concentration does not facilitate the exercise of market power.<sup>4</sup>

At the firm or (for multiproduct firms) business unit level, the revisionist view implies that market share should appear as the primary determinant of profitability in cross section regressions, while market concentration should have no impact. David Ravenscraft (1983) checked these predictions with FTC Line of Business data.<sup>5</sup> He found the impact of share on business unit profitability to be positive and highly significant, while the coefficient of concentration in the same regression was *negative* and significant. Ravenscraft interpreted his results as providing strong support for the revisionist argument that the significance of concentration in traditional industry-level cross-section regressions arises because concentration is correlated with share (and thus efficiency) differences, not because it facilitates collusion. Stephen Martin has recently obtained similar results in a simultaneous equations analysis of the FTC data. The strong relation between market share and profitability found by these and other authors is difficult to interpret within the classical tradition, given the apparent absence of important scale economies in most industries.<sup>6</sup>

A third tradition, which I will call *managerial*, has yet another set of implications for business unit profitability. Business

<sup>2</sup>Leonard Weiss (1974) provides a survey of cross-section studies in the classical tradition; see also F. M. Scherer (1980, ch. 9).

<sup>3</sup>Efficiency should not be interpreted in narrow process terms here. A product innovation may simply make a firm more efficient in the production of the Lancasterian characteristics it supplies to an existing market. While product innovations that yield true differentiation (by creating something approaching a new market) cannot be formally modeled in this fashion, it seems appropriate to think of nondramatic product innovations in efficiency terms for purposes of positive analysis of profitability.

<sup>4</sup>This new, revisionist view seems to have been articulated explicitly first by Harold Demetz (1973); see also Sam Peltzman (1977). Interesting formal models consistent with this view have recently been developed by Boyan Jovanovic (1982), S. A. Lippman and R. P. Rumelt (1982), and others. It is important to note that something like the classical notion of entry or mobility barriers (Richard Caves and Michael Porter, 1977) must be invoked to explain why imitation does not suffice to eliminate efficiency differences among firms in the revisionist model.

<sup>5</sup>Scherer (ch. 9) reviews earlier studies of the effects of market share. Most obtained results broadly consistent with those of Ravenscraft and Stephen Martin (1983) but used data sets apparently inferior to theirs.

<sup>6</sup>See Scherer (ch. 4) for an excellent survey of the available evidence on economies of scale.

schools and management consultants exist because it is widely believed that some firms are better managed than others and that one can learn important management skills that are not industry specific. In a widely acclaimed best seller, Thomas Peters and Robert Waterman, Jr. (1982) stress the importance of firm-level efficiency differences based in large measure on differences in "organizational cultures." Dennis Mueller (1977, 1983) has recently reported econometric results implying the existence of substantial, long-lived differences in measured firm profitability. When profit rates in 1950 are taken into account, Mueller (1983) finds that concentration has a significant *negative* coefficient in an equation explaining projected firm profit rates in 1972, and industry effects in general are relatively unimportant.

Both the revisionist and managerial alternatives to the classical tradition are based on plausible arguments and suggestive evidence. But I do not think that it has been shown that the classical attention to the industry was in any sense a mistake: case studies of real markets clearly reveal important differences. Why, then, do conventional market-level variables perform poorly or perversely when firm or share effects are included in cross-section regressions?

One probable reason comes readily to mind. It has long been recognized that we have very imperfect measures of the classic dimensions of market structure and basic conditions. Conditions of entry have proven particularly difficult to measure in a satisfactory fashion. Moreover, the link between the real, economic profitability dealt with in theoretical discussions and the accounting returns used in empirical work is weakened by inflation (Geoffrey Whittington, 1983), depreciation policy (Thomas Stauffer, 1971; Franklin Fisher and John McGowan, 1983), risk (myself, 1981), and both cyclical (Leonard Weiss) and secular (Ralph Bradburd and Richard Caves, 1982) disequilibria.<sup>7</sup>

Conventional, classical industry-level variables may thus perform poorly at least in part because they are poor, incomplete measures of the (classical and other) market effects present in available data. Since many of the usual classical industry-level variables are endogeneous in the long run, and it is difficult to formulate enough noncontroversial exclusion restrictions to identify all parameters of interest, it is not clear that problems of measurement and disequilibrium can be successfully attacked by structural modeling using available cross-section data.

## II. Methods and Data

Instead of attempting structural analysis, this study employs a simple analysis of variance framework that allows us to focus directly on the existence and importance of firm, market, and market share effects without having to deal simultaneously with specific hypotheses and measurement issues related to their determinants. Specifically, I deal in all that follows with the following basic *descriptive* model:

$$(1) \quad r_{ij} = \mu + \alpha_i + \beta_j + \gamma S_{ij} + \epsilon_{ij},$$

where  $r_{ij}$  is the (accounting) rate of return of firm  $i$ 's operations in industry  $j$ ,  $S_{ij}$  is its market share, the  $\alpha$ 's are firm effects, the  $\beta$ 's are industry effects,  $\mu$  and  $\gamma$  are constants, and the  $\epsilon$ 's are disturbances. The assumptions that market share enters linearly in (1) and that  $\gamma$  is the same for all industries are made mainly for comparability to the literature, though both also simplify computation and interpretation. The 1975 FTC Line of Business data set, which I use, contains information on large multidivisional firms. Such information is clearly required to separate firm and industry effects in (1).

While none of the coefficients in (1) can be given a defensible structural interpretation, analysis of that model as a whole can shed

<sup>7</sup>An additional accounting problem arises with business unit data: the allocation of shared assets among individual lines of business is inevitably somewhat arbitrary. If firms follow similar rules of thumb for doing

this, spurious industry effects can be added to business unit data.

light on the relative merits of at least the extreme versions of the classical, revisionist, and managerial positions. An extreme classical, for instance, would expect the  $\beta$ 's to differ substantially with  $\alpha_i = \gamma = 0$  for all  $i$ . Estimates consistent with these expectations would of course not exclude the possibility that industry effects simply reflect industry-wide differences between accounting and economic rates of return or industry-level disequilibria, with variations in monopoly power of little or no importance. But a finding that the  $\alpha$ 's and  $\gamma$  did not differ significantly from zero would cast doubt on extreme managerial or revisionist positions.

The implications of these last two positions for the parameters of equation (1) are slightly less clear cut. An extreme revisionist would presumably expect a large  $\gamma$  with all the  $\alpha$ 's and  $\beta$ 's near zero if the  $r_{ij}$  were observations on *equilibrium* rates of return. But, since our data are in fact for a single year and thus reflect the effects of cyclical and other short-run industry-level disequilibria, an extreme revisionist would not likely be surprised to find significant differences among the  $\beta$ 's estimated here. Similarly, an extreme managerial position might be that variations in the  $\alpha$ 's should be much more important in equilibrium than those in the  $\beta$ 's or in the  $\gamma S_{ij}$  terms. But an extreme managerialist would also not likely be surprised to find differences in the  $\beta$ 's in a single year's data. Moreover, firm-level efficiency differences might affect business unit profitability through the revisionist mechanism, so that firm-level and share effects might be hard to distinguish. (I investigate this possibility below.)

Using firm and industry dummy variables, I first use ordinary least squares (fixed effects estimation) and the usual  $F$ -statistics to test for the *existence* of market effects (nonidentical  $\beta$ 's), firm effects (nonidentical  $\alpha$ 's), and share effects (nonzero  $\gamma$ ) in (1) and the natural special cases thereof. To analyze the *importance* of these effects, I treat the actual  $\alpha$ 's,  $\beta$ 's,  $S$ 's, and  $\varepsilon$ 's in any particular sample as (unobservable) realizations of random variables with some joint population distribution. Under the usual assumption that  $\varepsilon$  is distributed independently of the other variables, the population variance of  $r$  can be

decomposed as follows:

$$\begin{aligned} (2) \quad \sigma^2(r) &= \sigma^2(\alpha) + \sigma^2(\beta) + \gamma^2 \sigma^2(S) \\ &\quad + \sigma^2(\varepsilon) + 2\rho(\alpha, \beta)\sigma(\alpha)\sigma(\beta) \\ &\quad + 2\gamma\rho(\alpha, S)\sigma(\alpha)\sigma(S) \\ &\quad + 2\gamma\rho(\beta, S)\sigma(\beta)\sigma(S), \end{aligned}$$

where the  $\rho$ 's are correlation coefficients and the  $\sigma$ 's are standard deviations. Depending on which effects are revealed to exist by the analysis of (1), I estimate either (2) or a special case thereof to provide information on the importance of the determinants of observed profitability. Estimates of (2) relate directly to the predictions of the alternative traditions discussed above. The particular (random effects) estimation techniques used in this phase of the analysis are presented in Section III.

In most of the statistical literature concerned with variance decomposition, orthogonality of effects is assumed, so that covariance terms like the last three on the right of (2) are set to zero.<sup>8</sup> But that assumption is not plausible here. If an important attribute of efficient firms is their ability to pick profitable industries in which to operate, for instance, we would expect this feature of the data generation process on which I must condition the estimates to produce a positive  $\rho(\alpha, \beta)$ . Similarly, one expects efficient firms to have low costs and high shares, so that  $\rho(\alpha, S)$  should be positive. Finally, if one knows that some particular  $S_{ij}$  is above average, one's conditional expectation must be that concentration in market  $j$  is above average. If one expects industry concentration to be positively related to industry profitability, it then follows that one expects  $\rho(\beta, S)$  to be positive. On the other hand, since  $\varepsilon$  captures all profitability differences unrelated to firm, industry, or market share differences, the assumption that it is orthogonal to those effects seems natural and reasonable.

The strength of this descriptive approach is that my conclusions about the three relevant types of effects will not be conditioned

<sup>8</sup>See, for instance, S. R. Searle (1971, chs. 9–11).

by maintained hypotheses regarding the determinants of those effects. I can focus directly on the general implications of extreme classical, revisionist, and managerial positions without having to deal with issues of endogeneity or identification. In addition, if one doubts a priori that any of these extreme positions is tenable, one can look to quantitative evidence on the importance of firm, market, and market share effects and the correlations among them to suggest tenable compromise positions as well as questions and strategies for future research.

One important issue of research strategy can be very easily addressed within this framework: is it defensible to work with industry-level data? Given the central role of profits in industrial economics, the answer must depend critically on how important industry effects are in determining industry rates of return. Only if industry profitability mainly reflects industry-level effects can one hope that hypotheses about the (classical, accounting, disequilibrium, and other) determinants of those effects can be productively tested with industry-level data. If  $R_j$  is the (appropriately weighted) average rate of return of business units operating in industry  $j$ , equation (1) implies

$$(3) \quad R_j = \mu + \beta_j + \text{terms in } \alpha\text{'s, } S\text{'s, and } \varepsilon\text{'s.}$$

Industry-level analysis would seem to be sensible if and only if (estimates of)  $\sigma^2(\beta)$  are large relative to the cross-section variance of the  $R_j$ , so that industry-level differences are important determinants of industry average rates of return.

All empirical results reported below are based on a subset of the 1975 data on individual business units gathered and compiled by the FTC's Line of Business Program. These business units account for about one-half of manufacturing sales and about two-thirds of manufacturing assets. (See Ravenscraft and the sources he cites for detailed discussions of the FTC data.) In order to minimize the influence of newly born and nearly dead operations, only the 3,816 business units present in the FTC data in both 1975 and 1976 were considered. Sixteen industries that appeared to be primarily residual classifications were excluded because they

seemed unlikely to correspond even approximately to meaningful markets.<sup>9</sup> This removed 340 observations. In order to mitigate scale-related heteroscedasticity problems and to focus on the revisionist mechanism (as distinguished from scale economies), the 1,070 remaining observations with market shares of less than 1.0 percent were excluded. (Note that none of these involve small firms; all are small divisions of the 471 large firms sampled by the FTC.) Finally, one outlier (with operating losses exceeding sales and assets/sales several times larger than other business units in its industry) was excluded before analysis began. Our final data set contained 1,775 observations on business units operated by 456 firms in 242 of the 261 FTC manufacturing industries.

In equation (1),  $r_{ij}$  was measured as the ratio of operating income to total assets, expressed as a percentage. This quantity provided an estimate of the total pre-tax rate of return (profits plus interest) on total capital employed; it seemed superior on theoretical grounds to the frequently employed price-cost margin as a measure of profitability.<sup>10</sup> Its mean was 13.66, and its variance,  $s^2(r)$ , was 348.97. For each industry in the sample, I also computed the asset-weighted average rate of return,  $R_j$ . The mean and variance of these 242 numbers were 13.08 and 86.91 ( $\equiv s^2(R)$ ), respectively. For  $S_{ij}$  I used estimates computed and kindly supplied by Ravenscraft.<sup>11</sup> The mean percentage market share in this sample was 6.14, with a variance of 59.23 ( $\equiv s^2(S)$ ).

### III. Empirical Findings

Figure 1 summarizes the results of least squares estimation of equation (1) and re-

<sup>9</sup>The industries dropped were the following: 20.29, 22.12, 23.06, 23.07, 24.05, 25.06, 28.17, 29.03, 30.06, 32.18, 33.13, 34.21, 35.37, 36.28, 37.14, and 39.08.

<sup>10</sup>Capital markets serve to equalize (risk-adjusted) rates of return on investment, not on sales. The case for using rate of return on sales as a measure of the Lerner index rests a belief that accounting average cost is a good proxy for marginal cost, which I doubt, and the undeniable proposition that sales are measured more accurately than assets.

<sup>11</sup>This variable is 100 times the variable *MS* used by Ravenscraft.

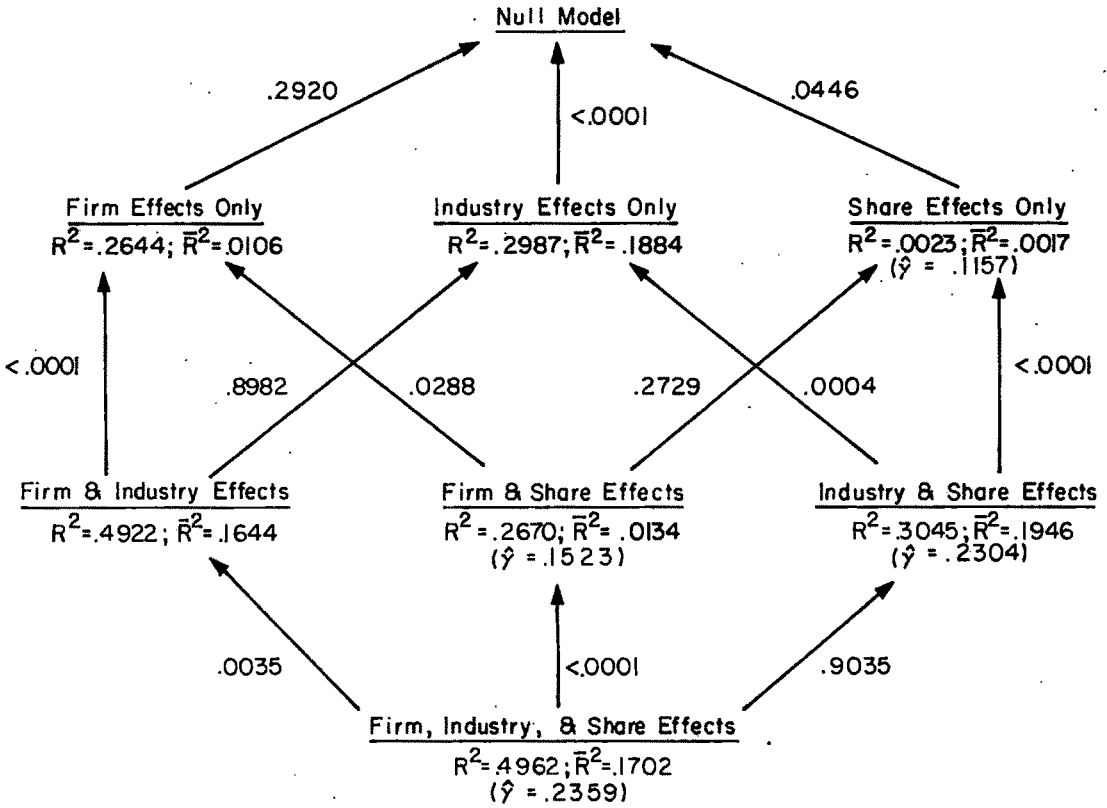

FIGURE 1

stricted models excluding one or more of the three effects with which we are concerned. The values of the ordinary and adjusted  $R^2$  statistics are shown,<sup>12</sup> along with the estimates of  $\gamma$  obtained from models with a share effect. Each arrow corresponds to the imposition of a restriction that one of the three effects discussed above is absent; the number next to each arrow is the probability level at which a standard  $F$ -test rejects that restriction. These numbers are referred to simply as  $P$ -levels in what follows.

All the high  $P$ -levels in Figure 1, which indicate failure to reject the null hypothesis at conventional levels, are generated by tests

for firm effects (arrows pointing to the right in Figure 1). These data imply that firm effects simply do not exist. In the absence of industry effects, the null hypothesis that the realized  $\alpha$ 's are identical can be rejected at the 29.2 percent level (no share effect) or the 27.3 percent level (share effect present). These results might lead a Bayesian analyst with a strongly managerial prior to accept the existence of firm effects. But both tests conducted in the presence of industry effects produce  $F$ -values less than unity, which provide absolutely no support for the existence of firm effects. Firm effects seem to approach significance only when firm-specific dummy variables serve as proxies for industry effects. When industry effects are controlled for, firm effects fade into insignificance. The absence of a similar interaction between firm and share effects indicates that firm effects do not operate through the revisionist mechanism to

<sup>12</sup>The adjusted  $R^2$  is equal to  $1 - [s^2(\epsilon)/s^2(r)]$ , where  $s^2$  is the usual unbiased estimator of the variance, so that changes in this quantity, rather than in  $R^2$  itself, correspond to changes in an unbiased estimator of the fraction of variance "explained."

any noticeable extent. Firm dummies do not serve as proxies for market share, and there is no difficulty disentangling firm and share effects.

In sharp contrast, all tests for the existence of industry or share effects produce significant results. All four tests of the null hypothesis of no share effects (arrows pointing to the left in Figure 1) signal rejection at  $P$ -levels below 4.5 percent, while the null hypothesis of no industry effects is always rejected at below the 0.01 percent level (vertical arrows in Figure 1).<sup>13</sup>

Let us now consider the importance of share and industry effects, postponing until Section IV a discussion of the implications of the absence of firm effects in these data. It is most instructive first to present an informal treatment based on information in Figure 1 and then to employ the relevant special case of (2) in a more systematic analysis.

Comparing adjusted  $R^2$ s of models not involving firm effects, market effects seem to account for between 18.84 and 19.29 percent of the sample variance of  $r$ . Following the discussion of equation (3), above, note that these percentages correspond to 75.65 and 77.46 percent of  $s^2(R)$ , the sample variance of industry average rates of return. Industry effects thus seem to be quite important, apparently accounting for the bulk of inter-industry differences in accounting rates of return. The industry seems an easily defensible unit of analysis.

On the other hand, the adjusted  $R^2$ s in Figure 1 indicate that market share effects add only between 0.17 and 0.62 percent to variance explained. Similarly, using  $\gamma = 0.2304$  from Figure 1,  $\gamma^2 s^2(S)$  amounts to only 0.90 percent of  $s^2(r)$ . It is interesting to note that in Ravenscraft's paper, which focuses on share effects, this ratio is even

smaller; it is between 0.53 percent ( $GLS$ ) and 0.82 percent ( $OLS$ ).<sup>14</sup> While Ravenscraft also uses 1975 Line of Business data, he uses the ratio of operating income to sales to measure profitability, does not delete "miscellaneous" industries or observations with small shares, uses classical variables like concentration in place of industry dummies, and attempts (in his  $GLS$  estimates) to correct for a complex pattern of heteroscedascity. The statistical significance but quantitative unimportance of market share effects thus seems a robust feature of these data.

One final pattern in the statistics presented above deserves mention. Market share adds more to adjusted  $R^2$  in the presence of industry effects (0.62 vs. 0.17 percent), and industry effects add more in the presence of share effects (19.29 vs. 18.84 percent). This sort of complementarity is suggestive of a negative correlation between market share and industry effects. Pointing in the same direction are the drops in the  $P$ -levels associated with share effects when industry effects are added and the corresponding changes (not visible in Figure 1) in the  $P$ -levels associated with industry effects. Finally, the fact that the estimate of  $\gamma^2 s^2(S)$  discussed above exceeds the contribution of share effects to adjusted  $R^2$  is also suggestive of a negative correlation between share and industry effects. (See equation (5) below.)

Let us now provide a more systematic analysis of the issues raised in the preceding three paragraphs. With no firm effects present, the relevant special cases of (1) and (2) are the following:

$$(4) \quad r_{ij} = \mu + \beta_j + \gamma S_{ij} + \varepsilon_{ij},$$

$$(5) \quad \sigma^2(r) = \sigma^2(\beta) + \gamma^2 \sigma^2(S) + \sigma^2(\varepsilon) \\ + 2\gamma\rho(\beta, S)\sigma(\beta)\sigma(S).$$

Readers uninterested in estimation technique and persuaded by the evidence presented above bearing on (5) may wish to glance briefly at Table 1, which summarizes the

<sup>13</sup> This is a very conservative statement of the strength of the evidence for the presence of industry effects. The  $F$ -statistics and corresponding restricted models are the following:  $F(241, 1533) = 2.709$ , null model;  $F(241, 1532) = 2.762$ , share effects only;  $F(241, 1078) = 2.007$ , firm effects only;  $F(241, 1077) = 2.033$ , firm and share effects. I calculate the probability of obtaining  $F$ s above any one of these values under the null hypothesis to be less than  $10^{-13}$ .

<sup>14</sup> The necessary statistics are in Tables 1 and A.1 of Ravenscraft.

TABLE 1—ESTIMATED VARIANCE DECOMPOSITIONS

Name	Population			Sample		
	Component	Estimate	Percentage	Component	Estimate	Percentage
Market	$\sigma^2(\beta)$	68.466	19.59	$\sigma^2(\beta)H$	67.905	19.46
Share	$\gamma^2\sigma^2(S)$	2.182	0.62	$\gamma^2\sigma^2(S)\{1-(1-H)\rho^2\}$	2.182	0.63
Covariance	$2\gamma\rho\sigma(\beta)\sigma(S)$	-2.177	-0.62	$2H\gamma\rho\sigma(\beta)\sigma(S)$	-2.159	-0.62
Error	$\sigma^2(\epsilon)$	281.049	80.41	$\sigma^2(\epsilon)$	281.049	80.54
Total	$\sigma^2(r)$	349.520	100.00	$s^2(r)$	348.977	100.00

Note: See text for sources and definitions. Totals may not add because of rounding.

results developed below, and then skip to Section IV.

Ordinary least squares estimation of (4), which appears in Figure 1 as the "Industry and Share Effects" model, yields a consistent and unbiased estimate of 281.05 for  $\sigma^2(\epsilon)$ . Following Searle's (chs. 9-11) treatment of variance components estimation in unbalanced models, I next compute consistent "analysis-of-variance" estimates of the remaining quantities on the right of (5).

Let the operator *ESS* mean "expected sum of squares about the sample mean," let  $N$  be the total number of observations, let  $N_j$  be the number of observations in industry  $j$ , and let  $M$  be the total number of industries. A bit of algebra yields

$$(6) \quad ESS(r_{ij} - \gamma S_{ij}) \\ = (N-1)\sigma^2(\epsilon) + (N-G)\sigma^2(\beta),$$

where

$$(7) \quad G = \sum_{j=1}^M (N_j)^2 / N.$$

If all industries had only one firm,  $G$  would equal one. If there were only one industry,  $G$  would equal  $N$ , since industry effects would not contribute to overall variance. In these data,  $G = 15.55$ . Using  $\gamma = .2304$  and  $\sigma^2(\epsilon) = 281.05$  from above, setting the expectation on the left of (6) equal to its sample value, and solving yields an estimate of 68.47 for  $\sigma^2(\beta)$ . This is equal to 19.62 percent of the sample variance of the  $r_{ij}$  and 78.78 percent of the sample variance of the  $R_j$ . The quantitative importance of industry effects

and the defensibility of industry-level analysis are again clear.<sup>15</sup>

In order to estimate the two remaining terms on the right of (5), it is necessary to be more specific about what is meant by a non-zero population correlation between market share and market effects. Imagine the data generation process first fixing the  $N_j$ , then drawing the  $\beta$ 's independently from their unconditional distribution, and finally drawing the  $S$ 's for each industry from the conditional distribution determined by the value of  $\beta$  previously drawn. Assume without loss of generality that the unconditional mean of the  $\beta$ 's is zero and of the  $S$ 's is  $\mu_s$ . I then impose the following assumptions:

(8a)

$$E(S_{ij}S_{kj}) = \begin{cases} (\mu_s)^2 + \sigma^2(S), & i = k \\ (\mu_s)^2 + \sigma^2(S)\rho^2(\beta, S) & i \neq k \end{cases}$$

$$(8b) \quad E(\beta_j S_{ij}) = \rho(\beta, S)\sigma(\beta)\sigma(S).$$

The first part of (8a) and (8b) are not restrictive; the second part of (8a) is consistent with but does not impose normality. These expectations are taken with respect to the unconditional population distribution,

<sup>15</sup>As a final check on the robustness of this conclusion, I computed MIVQUEO estimates of orthogonal firm, market, and error variance components of  $r_{ij}$  and  $(r_{ij} - \gamma S_{ij})$ . (See H. O. Hartley et al., 1978.) I obtained estimates of  $\sigma^2(\beta)$  of 62.03 and 64.88, respectively. This very different technique thus produced estimates very close to those in the text, further strengthening the case for the quantitative importance of industry effects in these data.

but they are *conditional* on the assignment of firms to markets. Similarly, for  $h \neq j$ ,  $E(\beta_h \beta_j) = E(\beta_h S_{ij}) = 0$ , and  $E(S_{ih} S_{kj}) = (\mu_s)^2$ .

Let  $r_j$  be the *unweighted* mean of the rates of return of business units in industry  $j$ . Then if (4) is the true model, (8a) and some algebra yield

$$(9) \quad ESS(r_{ij} - r_j) = (N - M)\gamma\sigma^2(S) \\ \times [1 - \rho^2(\beta, S)] + (N - M)\sigma^2(\varepsilon).$$

The quantity on the left is the expected sum of squared residuals from a regression of the  $r_{ij}$  on  $M$  industry dummy variables. This regression appears as the "Industry Effects Only" model in Figure 1. Use of (8) and a bit more algebra yields

$$(10) \quad ESS(r_{ij})/(N - 1) = E[\sigma^2(r)] \\ = H\sigma^2(\beta) + \gamma^2\sigma^2(S)[1 - (1 - H)\rho^2(\beta, S)] \\ + \sigma^2(\varepsilon) + 2H\gamma\rho(\beta, S)\sigma(\beta)\sigma(S),$$

where

$$(11) \quad H = (N - G)/(N - 1).$$

Equation (10) provides a decomposition of the *sample* variance of business unit profitability corresponding to the decomposition of the *population* variance given by (5).

Setting expectations equal to sample values, solving (9) for  $\gamma\sigma(S)$  and substituting into (10), an equation is obtained involving  $\rho(\beta, S)$ , sample statistics, and estimates derived above. A search of the interval  $(-1, +1)$  reveals a unique root; the estimated value of  $\rho(\beta, S)$  is  $-0.089$ . This confirms the negative correlation between industry and share effects. Equation (9) then yields an estimate of 2.182 for  $\gamma^2\sigma^2(S)$ . As this is only about 3.2 percent of the estimated value of  $\sigma^2(\beta)$ , the unimportance of share effects is also confirmed. Table 1 reports the estimated population and sample decompositions, corresponding to equations (5) and (10), respectively, implied by these estimates.

#### IV. Conclusions and Implications

The analysis of Section III indicates that the 1975 FTC Line of Business data provide strong support for the following four empirical propositions:

PROPOSITION 1: *Firm effects do not exist.*

PROPOSITION 2: *Industry effects exist and are important, accounting for at least 75 percent of the variance of industry rates of return on assets.*

PROPOSITION 3: *Market share effects exist but account for a negligible fraction of the variance of business unit rates of return.*

PROPOSITION 4: *Industry and market share effects are negatively correlated.*

The apparent nonexistence of firm effects is somewhat surprising. This finding is perfectly consistent with substantial intra-industry profitability differences, which Table 1 shows to be present in these data. The absence of firm effects in (1) merely means that knowing a firm's profitability in market  $A$  tells nothing about its likely profitability in randomly selected market  $B$ . This is consistent with the conglomerate bust of the past decade and with a central prescriptive thrust of Peters and Waterman (ch. 10): wise firms do not diversify beyond their demonstrated spheres of competence. The nonexistence of firm effects suggests that Mueller's (1983) persistent firm-level profitability differences are traceable to persistent differences at the business unit or industry level, combined with relatively stable patterns of activity at the firm level.<sup>16</sup>

The finding that industry effects are important supports the classical focus on industry-level analysis as against the revisionist tendency to downplay industry differences.

<sup>16</sup> Using firm and industry dummy variables to analyze FTC Line of Business data, John Scott (1984) finds significant firm effects on R&D intensity. This finding indicates that the absence of firm effects is not in any sense built into the FTC data. Since R&D spending reflects policy rather than performance, it is not surprising that firm effects show up there but not here.

But it is important to note that my analysis is generally silent on the merits of classical models and hypotheses. The empirical analysis here is basically descriptive, not structural. The results cannot exclude the possibility that industry-level profitability differences in 1975 were dominated by the effects of the severe recession and energy price shocks that were buffeting the economy. Though 1975 was an outlier in several respects, these considerations should serve to remind us that cyclical and other short-run disequilibrium effects are present in observed rates of return in any single year cross section. And there is no reason to suppose that such effects are uncorrelated with classical industry-level variables. This study cannot be interpreted as supporting an uncritical return to classical cross-section regressions. Finally, it is important to recognize that 80 percent of the variance in business unit profitability is unrelated to industry or share effects. While industry differences matter, they are clearly not all that matters.

The statistical significance of market share in my fixed-effects regressions is consistent with previous studies that have reached revisionist conclusions. I depart from those studies by directly examining the importance of market share in explaining variations in business unit profitability. My finding that share matters but doesn't matter much might seem to justify ignoring the revisionist mechanism in future research and policymaking. I think that would be a mistake.

First, the estimated coefficient of market share is quite large in equations with industry dummy variables. The "Industry and Share Effects" estimate of  $\gamma = .2304$  reported in Figure 1 implies that an increase of market share from 10 to 50 percent is on average associated with an increase of 9.2 percentage points in  $r_{ij}$ . Average profitability differences of this magnitude cannot sensibly be ignored, whatever their cause.

Second, even if the revisionist mechanism is unimportant on average in explaining profitability differences, it may be of central importance in some markets or classes of markets. The coefficient of share is constrained to be equal across industries in our regressions, even though a large number of authors have found substantial and (to some

extent) systematic differences in the profitability/share relation across industries. Mueller (1983), for instance, finds the coefficient of market share in a profitability equation rises in cross section with increases in industry advertising intensity, which he interprets as reflecting basic conditions that make possible product differentiation.<sup>17</sup> The basic revisionist mechanism seems too plausible to dismiss entirely; we ought instead to investigate the *industry-level* factors that affect its nature and importance.

Finally, the negative correlation between market share and industry effects is surprising indeed. Since concentration and market share are positively correlated, this finding is perfectly consistent with the negative concentration coefficients obtained by Ravenscraft, Martin, and Mueller (1983) in cross-section profitability regressions. Moreover, my results imply that those coefficients cannot be made to change sign by obvious respecification along classical lines.

One plausible explanation for negative concentration coefficients that also applies to negative values of  $\rho(\beta, S)$  has been advanced by Martin. He argues that capital-intensive, concentrated industries were hit hardest by recession and energy shocks in 1975 and that these same disequilibrium effects swamped any long-run effects of concentration on collusion. Note, however, that Ravenscraft finds that concentration has a *positive* sign in industry-level profitability regressions with these same data. At the very least, all this suggests the value of gathering and using panel data that would permit explicit analysis of cyclical and secular disequilibria.

# A Theory of Contractual Structure in Agriculture

By MUKESH ESWARAN AND ASHOK KOTWAL\*

Agricultural tenancy will continue to fascinate economists until the main riddle it poses is satisfactorily resolved. The challenge is to explain not only the existence of sharecropping, but also the existence of fixed rental and fixed wage contracts. The dominant contractual form can vary with the crop, the prevailing technology, the extent of market development, and other characteristics of the economic and social environment. Sometimes two or all three types of contracts seem to coexist in the same area. A general framework that could give convincing explanations of not only the existence of all three types of contracts but also of their spatial and temporal variation, and thus of their links with the economic environment, has yet to emerge.

There are three types of explanations that have been offered for the existence of different tenurial contracts:<sup>1</sup> (i) tradeoff between risk sharing and transaction costs, (ii) screening of workers of different qualities, and (iii) market imperfections for inputs besides land.

Steven Cheung (1969) postulated that sharecropping offers the advantage of risk sharing while the other two contracts involve lower transaction costs. The optimal tradeoff in a given set of circumstances would then determine the dominant contractual form.<sup>2</sup>

There are two difficulties with this view. First, the argument that risk sharing is the main motivation behind sharecropping lacks empirical support (Chandrashekar Pant, 1981; C. H. Hanumantha Rao, 1971; K. Chao, 1983). Second, the tradeoff argument lacks credibility as there is no reason to believe that sharecropping involves greater transaction costs than a wage contract if transaction costs include supervision costs, as they should.<sup>3</sup>

William Hallagan (1978) and David Newbery-Joseph Stiglitz have used screening models to explain the existence of different contracts.<sup>4</sup> The main problem warranting sharecropping is envisaged to be the asymmetry of information about tenants' abilities; different contracts are needed to sort tenants out by their abilities. We believe that the assumption of ignorance on the part of landlords about tenants' abilities is quite inappropriate for most rural communities. Typically, there is little mobility, thus information about abilities and assets is easily available. Moreover, screening models cannot explain why a certain contractual form might predominate in one area while quite another form predominates elsewhere.<sup>5</sup> Just as the coexistence of contracts (if present) needs to be explained, a lack of coexistence also requires explanation. Screening models

<sup>1</sup>For a comprehensive recent survey of tenancy models, see Hans Binswanger and Mark Rosenzweig (1982). The present discussion of the existing literature borrows heavily from it.

<sup>2</sup>Cheung and Joseph Stiglitz (1974) had considered production uncertainty as the only source of risk. But in response to the criticism that mixing wage and fixed

rental contracts would offer the same risk-sharing advantage as sharecropping, the more recent literature has considered other sources of risk (for example, David Newbery and Stiglitz, 1979), restoring the risk-sharing advantage to sharecropping. Newbery and Stiglitz point out that economies of scale would serve the same function.

<sup>3</sup>See Gerald Jaynes (1982) for a detailed critique of Cheung's argument. Also see Joseph Reid (1976).

<sup>4</sup>Franklin Allen (1982) uses a similar screening model that incorporates the unobservability of the quality of land in addition to the unobservability of the tenant's ability.

<sup>5</sup>For example, the dominant tenancy form in Japan was fixed rental while in East India it is sharecropping.

are also not capable of explaining the change in the contractual structure that has been observed to result from a change in technology or the development of markets. For example, tenancy contracts changed to wage contracts in India after the introduction of new technology in the 1960's (Rao, 1977, ch. 12); the sharecropping contracts in the post-bellum South of the United States changed to wage contracts with the advent of mechanization (Richard Day, 1967).

The most appealing view of tenancy is that it substitutes for the absence or imperfections of a market for some factor input besides land. The absence or incompleteness of markets can typically result from the high costs of quality enforcement. Recent literature has pointed out technical know-how (Joseph Reid, 1976), managerial ability (Clive Bell-Pinhas Zusman, 1979), bullocks (Christopher Bliss-Nicholas Stern, 1982), credit (Gerald Jaynes, 1982), and family labor (Pant, 1983) as examples of factors for which markets are highly imperfect. An effective way of gaining access to such a factor is to offer a self-monitoring (incentive) contract to the factor owner, involving him in the production process. The factor input is thus available only as a package deal with the factor owner's time. However, the self-monitoring contract does not have to be a share contract. The landlord could gain access to the tenant's supervision ability or to his bullocks by offering him a fixed rental contract. Why then does sharecropping exist?

Following Reid (1977) we envisage the landlord and tenant as both contributing unmarketed resources in a sharecropping arrangement. We view sharecropping as a partnership arrangement in which both agents have incentives to self-monitor.<sup>6</sup> Such a contract arises to mitigate morally hazardous behavior on the part of both agents—a phenomenon as yet unexplored in the literature. If all the monitoring of input qual-

ity is undertaken by a single agent, he becomes the sole residual claimant; in a wage contract it is the landlord, and in a fixed rental contract it is the tenant. The different contracts thus reflect different techniques of combining unmarketed productive inputs.<sup>7</sup> The choice of technique depends on exogenous parameters such as the endowment distribution across the classes of factor owners and the prevailing production technology. The equilibrium contractual structure emerges from the optimizing decisions of both landlord and tenant in a given environment. In order to facilitate the derivation of the testable implications of this view, we shall abstract from all considerations pertaining to risk in this paper. This abstraction enables us to make a comparison of the implications of the hypothesis that sharecropping exists to pool unmarketed resources with the implications of the conventional wisdom that it exists to share risk.

The paper is organized as follows. In Section I we present the general model of contractual choice in an agrarian economy. In Section II we solve the model and present comparative static results for a Cobb-Douglas specification. We use these results to explain some real world observations pertaining to agrarian contractual structures and changes therein. In Section III we discuss the limitations of the model and suggest extensions.

### I. The Model

Here we spell out our model of agricultural production that will enable us to endogenize the type of contractual arrangement (fixed wage, fixed rental, or sharecropping) that will prevail in a given setting. The model we construct is the simplest one that incorporates what we envisage to be the crucial features of agricultural production. It is our view that agricultural production entails the

<sup>6</sup> Bliss and Stern (p. 309) also view sharecropping as an arrangement that involves the pooling of managerial and cultivating skills. Peter Murrell (1983) points out that in the Philippines the word for sharecropping also means partnership.

<sup>7</sup> This idea is implicit in Reid's work on sharecropping (1977; 1976). In Reid (1979) this view is made explicit. We formalize the idea and relate it to the exogenous parameters of the social and economic environment.

use of certain unmarketed resources, and access to these resources is obtained by making their owners residual claimants. We believe this to be the most important determinant of the contractual structure of an agrarian economy and have therefore made it the cornerstone of our model of agrarian contracts. We focus on two specific unmarketed resources: the ability to supervise labor; and the managerial ability to make production decisions based on technical know-how and market information. These two abilities constitute the core of farm management.

Labor supervision is of crucial importance because in farming the output is very sensitive to the quality of effort; a slight mistiming in transplanting or the application of a wrong fertilizer mix, for example, can have disastrous consequences. Also, many farming activities are characterized by the fact that the quality of effort applied cannot be easily ascertained until after the work has been completed. The importance of the quality of effort on the one hand, and the inherent moral hazard problem of shirking on the other, imply that labor of itself is not an effective input; it is an aggregate of the labor hired and the supervision effort applied to reduce shirking that is an effective input into agricultural production. If  $L$  denotes the amount of labor hired and  $s$  the amount of time spent by a supervisor on supervising labor, we may define the "effective labor" input or "effort,"  $E$ , by

$$(1) \quad E = g(s, L; \epsilon),$$

where  $g$  is a linearly homogeneous aggregator which is increasing and concave in  $s$  and  $L$ , and  $\epsilon$  is a parameter ( $0 \leq \epsilon \leq 1$ ) characterizing the aggregator. The parameter  $\epsilon$  is introduced to capture the relative importance of supervision in a unit of effective labor, and is defined to be such that if  $\epsilon = 0$ , supervision is redundant, while increasing  $\epsilon$  implies that supervision is increasing in importance. An improvement in the technology of labor supervision would render supervisory effort less important and would therefore translate into a decrease in  $\epsilon$ .

In a tenancy contract, family labor is regarded as a crucial resource (Pant, 1983). Since it is easier to supervise one's own family labor than to supervise hired workers, a tenant may be considered to have labor-supervision abilities superior to those of a landlord. A tenancy contract should thus be considered not just as a contract to hire the labor of the tenant but, as well, the supervised labor of the family.

The efficiency of agricultural production is also crucially dependent on the quality of management decisions. Judicious choice of crops, proper land and water management, selection of inputs, and timely procurement and application of inputs are essential for successful farming. It involves decision making based on sound technical and market information. The choice of crops, for example, should depend on the expected changes in relative prices; water distribution should depend on the requirements of the specific technology; the choice and procurement of inputs should require the knowledge of the available inputs, their quality and prices, and the expected supply bottlenecks and shortages. Good production decisions must also depend on the knowledge of government tax-subsidy programs and of agricultural policy in general. Collecting such information and checking its reliability is a time-consuming process. The greater the time spent in gathering and assimilating information, the better is the quality of management decisions.<sup>8</sup> We shall, therefore, use the time devoted to such activities by the farm manager as a proxy for the managerial input.

We thus posit that agricultural production entails the use of four inputs: (i) management, which we represent by the time,  $t$ , spent by the entrepreneur on the activity; (ii) materials,  $M$ , which is an aggregate of such physical inputs as seeds, fertilizer fixed capital, etc.; (iii) labor effort,  $E$ , as defined in (1) above; and (iv) land,  $H$ , which we

<sup>8</sup> Bliss and Stern give an excellent account of the different managerial tasks important in agricultural production.

assume to be fixed and indivisible.<sup>9</sup> The output,  $q$ , of a farm may thus be written

$$(2) \quad q = \theta F(t, M, E, H),$$

where  $F$  is assumed to be a production function that is linearly homogeneous, increasing, and concave in its arguments. In (2),  $\theta$  is a positive random variable with an expected value of unity, intended to embody the effects of such stochastic factors as weather. Since we are explicitly abstracting from considerations pertaining to risk, the only role played by  $\theta$  is that it renders impossible the imputation of the amount of an input applied from knowledge of the levels of the other inputs and of the output. While the amounts of hired labor and material inputs are easily observable, supervision and management are not. This feature introduces the moral hazard problem of shirking in the provision of the supervision and management inputs in the event that they are provided by separate agents—as in sharecropping.

Substituting for  $E$  from (1), (2) may be rewritten as

$$(3) \quad q = \theta f(t, s, M, L, H; \epsilon),$$

where  $f$  is linearly homogeneous, increasing, and concave in its first five arguments.

In traditional societies, many exchange relationships are personalized and access to market information, scarce inputs, and government services is a matter of privilege. This privilege may stem from wealth, social position, or family connections. Rich landlords often dominate the local political bodies.<sup>10</sup> Access of any kind is correlated with the size of landholdings. Capital markets are usually

underdeveloped and access to credit is notoriously dependent on the ability to offer collateral, mostly land (Rao, 1977, pp. 138–42). In view of the limited ability of the marginal farmers and tenants to raise working capital, it is natural that it is the landlords who normally interact with traders and financial institutions. Landlords thus develop better avenues for the acquisition of productive market information—the government bureaucracy and the traders. In addition to these factors, landlords' families, with their higher wealth and social standing, are likely to have acquired better education than the laborers' families (Rao, 1977, p. 138). Landlords as a class, therefore, are more proficient in acquiring information on changing market conditions and technology than their tenants (Shigeru Ishikawa, 1981, pp. 168; Reid, 1979, p. 307; Lee Alston-Robert Higgs, 1982, p. 335). Resident landlords who are not alienated from farming and the rural scene are, therefore, likely to be much better suited for the role of overall decision making (i.e., general manager), while the tenant with his family labor force is better suited for the role of a labor supervisor (i.e., foreman).

For convenience we shall refer to the input  $t$  in (3) as "management" and to  $s$  as "supervision." We have argued above that landlords have superior abilities in management and tenants in supervision. We quantify this idea of differential abilities by means of two parameters,  $\gamma_1$  and  $\gamma_2$ . We assume that one hour of the landlord's (tenant's) time devoted to supervision (management) is equivalent to only a fraction  $\gamma_1$  ( $\gamma_2$ ) of one hour devoted to supervision (management) by the tenant (landlord). (Note that here and elsewhere in the paper, quantities subscripted by 1 refer to the landlord, those by 2 refer to the tenant.) An efficiency unit of management (supervision) will be assumed to be one hour of the landlord's (tenant's) time. Since market development tends to equalize access to know-how across agents by diffusing information, it would increase  $\gamma_2$  towards 1. Similarly, a substitution of the landlord's family labor for hired labor would increase  $\gamma_1$  towards 1 by eliminating the supervision advantage of tenants.

<sup>9</sup>It would be more realistic to make the plot size a choice variable controlled by the landlord and have a landlord enter into contracts of one of more variety with several tenants simultaneously. However, such a modification would greatly complicate the task of theorizing, without necessarily adding any new insights into the determination of contractual structure.

<sup>10</sup>See Rao (1977, pp. 186–87) for a discussion of the social and political power wielded by the rural rich in India.

We assume that the landlords and workers each have one unit of time which they must allocate between agricultural production and their alternative activities. The opportunity wage of a landlord is  $v$ , for a hired worker it is  $w$ , and for a labor-supervisor it is  $u$ , with  $u \geq w$ . The labor market is assumed to be competitive, and all opportunity incomes are assumed to be exogenously determined. The price of materials,  $p$ , is also assumed to be given.

The landlord has three options regarding the manner in which his land might be cultivated. First, he could self-cultivate by hiring unskilled labor and providing both management and supervision himself. This is the fixed wage contract. He could, instead, lease out the land to a tenant for a fixed lump sum rental. In this fixed rental contract, the tenant hires unskilled labor and provides both management and supervision himself. Finally, the landlord and the tenant could make a share contract in which the former provides management, the latter supervision, and output is shared. The share contract affords the opportunity for specialization—each agent performs the task at which he has the absolute advantage. In an arrangement in which management and supervision inputs are provided by different agents, the moral hazard of shirking arising from the unobservability of these inputs would be mitigated if both agents are made residual claimants. This is precisely what the share contract accomplishes. Thus sharecropping emerges in a natural fashion as a response to the possibility of achieving a superior input mix through resource pooling in the face of a moral hazard problem. Such an arrangement brings together superior inputs into production, but it suffers from the disadvantage of the disincentive effect arising from the fact that each of the two agents receives only a fraction of his marginal product.<sup>11</sup> These considerations, along with the opportunity incomes of the agents, will determine the contract that will emerge as the dominant one.

<sup>11</sup> This tradeoff has been pointed out by Bliss and Stern (p. 309).

We now turn to the determination of the optimal contract. For each type of contract we set up the optimization problem facing the agents.

#### A. Fixed Wage Contract

Assume the price of the agricultural output to be a constant,  $P$ . Under this type of contract, the landlord hires unskilled labor and allocates his time between management, supervision, and his alternative activity in order to maximize his expected net income:

$$(4) \quad \Pi_1^w = \max_{t_1, s_1, M, L} [Pf(t_1, \gamma_1 s_1, M, L, H) - pM - wL] + (1 - t_1 - s_1)v$$

$$0 \leq t_1 \leq 1, 0 \leq s_1 \leq 1, 0 \leq t_1 + s_1 \leq 1.$$

The term in the square brackets represents the landlords' expected income from cultivation and the other term the income from his alternative activity.

#### B. Fixed Rental Contract

Under this contract a worker leases the land for a fixed lump sum rental from the landlord. The expected net income of the tenant prior to paying the lump sum rental is given by

$$(5) \quad \Pi_2^r = \max_{t_2, s_2, M, L} [Pf(\gamma_2 t_2, s_2, M, L, H) - pM - wL] + (1 - t_2 - s_2)u$$

$$0 < t_2 \leq 1, 0 \leq s_2 \leq 1, 0 \leq t_2 + s_2 \leq 1.$$

We need to determine the fixed rent  $R$  that the landlord will demand of the tenant. Given the existence of a perfectly elastic supply of tenants, the rent on the land will be competed up until the tenant is at (or marginally above) his opportunity income  $u$ . Thus, we have

$$(6) \quad R = \max\{0, \Pi_2^r - u\}.$$

Under this type of contract, the landlord devotes all of his time to his alternative

activity. The landlord's income under the fixed rent contract is thus

$$(7) \quad \Pi_1^v = v + R.$$

### C. Share Contract

In the share arrangement, the landlord and the tenant each provide one of the unmarketed inputs and the profit (or output) is shared according to some endogenously determined, but mutually agreed upon, rule.

For the purpose of tractability, we make the assumption of complete specialization. It is easy to see that under this assumption the maximum expected output would be obtained when each agent provides the input in which he has the absolute advantage.

In what follows, it is convenient to define the restricted expected profit function,  $\Pi(t, s)$ , obtained by optimally choosing the amounts of labor and materials for parametrically given  $t$  and  $s$ :

$$(8) \quad \Pi(t, s) = \max_{M, L} Pf(t, s, M, L, H) - pM - wL.$$

We shall assume that the sharing rule takes the linear form:

$$(9a) \quad S_2 = \alpha + \beta \Pi,$$

where  $S_2$  is the expected profit share accruing to the tenant and  $\alpha, \beta$  are constants that are to be endogenously determined. The landlord's share of the expected profits must then be

$$(9b) \quad S_1 = -\alpha + (1 - \beta)\Pi.$$

The sharing rule (9) implies that what is shared is the revenue, net of labor and material costs, so that both agents bear part of the costs. This minor variation of the traditional assumption of output sharing is made purely for analytic convenience; the exercise can be repeated for an analogous output-sharing arrangement. In fact, it is typically the case that the share contract indicates not only the crop share but also

allocates the burden of costs. Implicit in (9) is the simplifying assumption that the labor and material costs are also shared in the same proportion as revenues. While this assumption can be relaxed, it would add little by way of insight to do so in what follows.

We now turn to the question of how the parameters  $\alpha$  and  $\beta$  of the share equations (9) are determined. The idea behind the procedure we use is simple. First, we examine the optimal decisions of the tenant and the landlord conditional on arbitrarily fixed values of  $\alpha$  and  $\beta$ . Then we step back and have the landlord choose  $\alpha$  and  $\beta$  in order to maximize his expected income subject to the tenant being at no less than his opportunity income. The landlord's choice is foresighted in that his decision is made under full knowledge of how the choice of  $\alpha$  and  $\beta$  will affect the ensuing equilibrium by affecting incentives.

Given the sharing rule (9), the tenant will choose the amount of time he will devote to supervision in order to maximize the variable component of his expected profits; he solves

$$(10) \quad \max_{s_2} \beta \Pi(t_1, s_2) + (1 - s_2)u, \quad 0 \leq s_2 \leq 1.$$

An analogous problem confronts the landlord; he must choose the amount of time to engage in management:

$$(11) \quad \max_{t_1} (1 - \beta) \Pi(t_1, s_2) + (1 - t_1)v, \quad 0 \leq t_1 \leq 1.$$

Following the literature, we shall assume that the two-person game we have here is resolved noncooperatively.<sup>12</sup> A natural assumption—and one which we invoke—is that each

<sup>12</sup> One could make a case that sharecropping involves cooperative rather than noncooperative behavior. If we assume the former, we would need to resort to bargaining theory to determine each agent's share. It is likely—as is true of the Nash bargaining solution—that the bargaining strength of each agent is determined by his payoff in the noncooperative resolution of the game being considered here.

agent entertains Nash conjectures, that is, he maximizes his expected profits taking as parametric the choice of the other agent.<sup>13</sup> The solution to (10) determines the Nash best response of the tenant:

$$(12a) \quad s_2 = \sigma(t_1; \beta),$$

while the solution to (11) yields the best-response function of the landlord:

$$(12b) \quad t_1 = \tau(s_2; \beta).$$

At a Nash equilibrium pair  $[t_1^*(\beta), s_2^*(\beta)]$ , equations (12a) and (12b) are simultaneously satisfied. The concavity of the production function implies that the restricted profit function (8) is concave in  $t$  and  $s$  (Theorem 2.20 in W. Erwin Diewert, 1973). This in turn, implies that for given  $\alpha$  and  $\beta$  the payoffs to the tenant and landlord (the objective functions of (10) and (11), respectively) are concave in  $t_1$  and  $s_2$ . Further, since the choice variables  $t_1$  and  $s_2$  are restricted to the compact convex set  $[0, 1]$  the existence of a Nash equilibrium is assured (see Theorem 7.4 in James Friedman, 1977). We shall assume that for given  $\alpha$  and  $\beta$ , the Nash equilibrium is unique.

The choices  $t_1$  and  $s_2$  in the Nash equilibrium will not, of course, depend on the parameter  $\alpha$ .<sup>14</sup> However, they will depend nontrivially on  $\beta$  since a change in this parameter, *ceteris paribus*, alters each agent's marginal remuneration and hence his incentives. For a given  $\beta$ , the landlord will set  $\alpha$  at a level that holds the tenant at (or barely above) his opportunity income. Thus  $\alpha$  satisfies

$$\alpha + \beta \Pi[t_1^*(\beta), s_2^*(\beta)] + [1 - s_2^*(\beta)]u = u,$$

so that

$$(13) \quad \alpha(\beta) = s_2^*(\beta)u - \beta \Pi[t_1^*(\beta), s_2^*(\beta)].$$

Finally, the landlord will choose  $\beta$  so as to maximize his expected income; the endogenous value,  $\beta^*$ , of  $\beta$  thus solves

$$(14) \quad \max_{\beta} -\alpha(\beta) + (1 - \beta) \Pi[t_1^*(\beta), s_2^*(\beta)] + [1 - t_1^*(\beta)]v.$$

We shall assume that  $t_1^*(\beta)$  and  $s_2^*(\beta)$  are continuous in their arguments. This ensures that a solution to the optimization problem (14) exists for  $\beta$  lying in the convex compact set  $[0, 1]$ . This completely endogenizes the parameters of the sharing rule (9). The landlord's expected income under the share contract is thus

$$\Pi_1^{sc} = -\alpha(\beta^*) + (1 - \beta^*) \times \Pi[t_1^*(\beta^*), s_2^*(\beta^*)] + [1 - t_1^*(\beta^*)]v.$$

Upon substituting for  $\alpha$  from (13), the above expression may be rewritten as

$$\Pi_1^{sc} = \Pi[t_1^*(\beta^*), s_2^*(\beta^*)] + [1 - t_1^*(\beta^*)]v + [1 - s_2^*(\beta^*)]u - u,$$

which, as one would expect, is the joint profit of the landlord and tenant, less the opportunity income of the latter.

Having determined the landlord's expected income under all three contractual arrangements, the determination of the arrangement that will prevail is, in principle, trivial: that contract would be chosen which maximizes the landlord's expected income. Since the supply of tenants is perfectly elastic, any rents that are generated accrue to the owner of the scarce resource, land: irrespective of the contract, the tenant earns only his opportunity income.

## II. Results

In this section we explicitly solve the model presented above for a Cobb-Douglas specification and present its comparative static results. The expected output of a farm, in the notation of the last section, is assumed to be

<sup>13</sup> It is interesting that substitution of the assumption of Nash behavior by Stackelberg behavior with the landlord as the leader results in the cooperative outcome.

<sup>14</sup> Unless, of course,  $\alpha$  is so negative that the tenant chooses not to participate at all in cultivation.

given by<sup>15</sup>

$$(15) \quad q = A t^{\delta_1} E^{\delta_2} M^{\delta_3} H^{\delta_4},$$

where  $A$ ,  $\delta_i$ ,  $i=1,2,3,4$  are positive constants and  $\sum_{i=1}^4 \delta_i = 1$ . The aggregator for the effort in (1) is also assumed to be Cobb-Douglas in structure:

$$(16) \quad E = s^\epsilon L^{1-\epsilon}, \quad 0 \leq \epsilon \leq 1.$$

The explicit solution of the model for Cobb-Douglas specifications (15) and (16) is presented in the Appendix. Since the restricted profit function (8) takes the form (A4) of the Appendix, which is concave in  $t_1$  and  $s_2$ , so are the objective functions (10) and (11) of the landlord and tenant, respectively, for any  $\beta \in [0,1]$  under sharecropping. Since  $t_1^*(\beta)$  and  $s_2^*(\beta)$  (given by A15a) and (A15b) of the Appendix), are continuous functions of  $\beta$ , so is the landlord's payoff (14). The solution to (14) determines the endogenous profit share of the tenant.<sup>16</sup> The determination of the fixed wage and fixed rental contracts are straightforward and are also presented in the Appendix.

We now present comparative static results, obtained by carrying out a series of parametric variations on the model. Parameter values in these exercises are chosen so as to facilitate a clear exposition of the forces that determine contractual structure. We note, however, that none of our conclusions—that are all qualitative in nature and are explained intuitively—are sensitive to the choice of parameter values. Three comparative static exercises are performed. We

analyze the impact of the following on the contractual structure:

(a) changes in the relative importance of the labor effort and management inputs (i.e., the effect of variations in  $(\delta_2/\delta_1)$ ;

(b) changes in the monitoring technology (i.e., the effect of variations in  $\epsilon$ );

(c) changes in the relative opportunity incomes of the two classes (i.e., effect of variations in  $(v/u)$ ).

A fourth exercise was conducted to study the variation of the optimal profit share,  $\beta^*$ , for a wide range in  $(\delta_2/\delta_1)$  and  $\epsilon$ .<sup>17</sup> The motivation for this exercise was to ask if our model would shed some light on the observed relative constancy of  $\beta$  in the neighborhood of one-half under a wide range of technological and market conditions.

The exogenous parameters of the model are those pertaining to the production function ( $A$ ,  $\epsilon$ ,  $\delta_i$ ,  $i=1, \dots, 4$ ), the distribution of abilities in management and supervision across classes ( $\gamma_1$  and  $\gamma_2$ )—henceforth referred to as the relative efficiency parameters—and the opportunity incomes ( $v$  and  $u$ ). In this entire section we normalize the price of output  $P$ , and the farm size  $H$  to unity. For a given configuration of parameter values, we numerically solve for the landlord's expected incomes under fixed wage and fixed rental contracts and compare the outcome with the landlord's expected income under the share contract.<sup>18</sup>

Figure 1 illustrates the partitioning of the relative efficiency (i.e.,  $\gamma_1$ ,  $\gamma_2$ ) parameter space according to the contractual arrangement that will prevail for parameter values noted in the figure. For low values of  $\gamma_1$  and  $\gamma_2$ , sharecropping prevails, since the diversification of activities (management and super-

<sup>15</sup>Note that (15) also lends itself to the interpretation of management as the monitoring of material input quality with  $t^{\delta_1} M^{\delta_3}$  as the aggregator that can be construed as the "effective material input."

<sup>16</sup>For any  $\beta \in [0,1]$  there are, in fact, two Nash equilibria, one of which is the trivial one  $t_1^*(\beta) = s_2^*(\beta) = 0$ ; since all inputs are essential, if either the landlord or the tenant applies zero effort, the Nash best response of the other is also to apply zero effort. Since this solution corresponds to the case in which there is no agricultural production at all, we shall restrict our attention in what follows to the nontrivial Nash outcome.

<sup>17</sup>For the chosen specification of the model, it turns out that  $\beta^*$  is invariant with respect to changes in opportunity incomes  $v$  and  $u$ . However, we would not expect this to be a feature of a more general specification.

<sup>18</sup>Note that under the fixed wage and fixed rental contracts, the entrepreneur has only one unit of time to allocate between management and supervision, while two units of time are available under a share contract. In order to be able to compare the outcomes of the various contracts without bias, we have chosen parameter values that yield interior solutions.

FIGURE 1. FRAGMENTATION OF RELATIVE EFFICIENCY PARAMETER SPACE ACCORDING TO DOMINANT CONTRACTURAL TYPE

(Parameter values:  $\delta_1 = 0$ ,  $\delta_2 = 0.2$ ,  $\delta_3 = \delta_4 = 0.25$ ,  $\varepsilon = 0.5$ ,  $A = 4$ ,  $p = w = 1$ ,  $u = 1.1$ ,  $v = 1.25$ .)

vision) required of the agents in the other two contractual arrangements render them relatively unprofitable. Such would be the case if the rural society is polarized into a landlord class alienated from day-to-day farm work and a working class devoid of managerial abilities. As markets develop, diffusing information and hence eliminating the disparity in managerial abilities between the two classes (i.e., as  $\gamma_2$  increases), sharecropping will give way to fixed rental contracts. To the extent that access to information is correlated with land ownership, a relatively uniform distribution of the latter would imply a high value of  $\gamma_2$ , rendering sharecropping less likely. In some states of India, where the distribution of land across the classes is highly skewed, sharecropping is commonly observed.

Sharecropping is often regarded as a backward or a feudal form of agriculture. This view is explained by Figure 1, according to which sharecropping would dominate when markets are either absent or underdeveloped and the class structure is polarized—two characteristics that are commonly associated with feudalism and backwardness.

If  $\gamma_2$  is small while  $\gamma_1$  is large, that is, if the workers lack managerial abilities and the landlords are not comparatively inept at supervision, wage contracts will obtain, as shown in Figure 1.

Absentee landlords typically appear to lease out their land under fixed rental contracts (Alston-Higgs; Bliss-Stern; Chao). This is quite consistent with our model: an absentee landlord typically does not provide any input at all apart from land and consequently sharecropping is not viable. Landowners who are engaged in some activity other than cultivation possess neither any supervisory abilities nor any advantage over the workers in access to information (i.e.,  $\gamma_1 \ll 1$  and  $\gamma_2 \approx 1$ ). The resulting contracts would therefore be of the fixed rental type.

Figure 1 may also be used to explain the rise of sharecropping in the postbellum South of the United States. With the abolition of slavery, the previously used supervision technology of the landlords was no longer feasible (i.e.,  $\gamma_1$  declined) and the absence of managerial ability among the emancipated slaves made sharecropping inevitable (Alston-Higgs; Reid, 1976). The lack of access of the freed men to credit and other agricultural inputs was probably also a contributing factor (Jaynes).

It is interesting to note that the ability to pool otherwise unobtainable resources under sharecropping allows the application of a superior input bundle to cultivation. This results in the possibility of the agricultural yield under sharecropping being higher than that under any other contract despite the disincentive effect operating in sharecropping. This may explain the observations reported by Bliss-Stern, and M. Mangahas et al. (1976), among others, that sometimes the yields under the share contract are higher than under alternative arrangements. In general, depending on the tradeoff between the advantage of a superior input combination and the disadvantage of the disincentive effect under sharecropping, the yield may compare favorably or unfavorably with other arrangements.

Figure 1 does not explain the coexistence of two or more types of contracts in the same geographical area. For ease and clarity we have cast our model in terms of only two

classes and one technology. It is easy to see that, in principle, the model could be extended to incorporate more than two classes, with each class differently endowed (i.e.,  $\gamma_1$  and  $\gamma_2$  are different across classes), and multiple technologies (for example, different crops). The introduction of this realistic feature of heterogeneity into the model would lead, in a natural fashion, to heterogeneity in the contractual structure in the same area at the same time. Thus, for example, absentee landlords may be found to lease out their land on a fixed rental basis to small farmers with some managerial ability but low opportunity incomes, while large farmers with access to market information might sharecrop with marginal farmers having none. At the same time, there can exist farmers who self-cultivate by hiring labor under wage contracts.

For what follows it is convenient to define the critical values,  $\gamma_1^c$  and  $\gamma_2^c$ , of the relative efficiency parameters  $\gamma_1$  and  $\gamma_2$ , respectively. The value  $\gamma_1^c$  ( $\gamma_2^c$ ) is that value of  $\gamma_1$  ( $\gamma_2$ ) at which, for given  $\gamma_2$  ( $\gamma_1$ ), the landlord would choose to switch from sharecropping to a fixed wage (fixed rental) contract, *ceteris paribus*. In other words,  $(\gamma_1^c, \gamma_2^c)$  denotes the coordinates of the point *A* in Figure 1. Much of the discussion to follow is cast in terms of  $\gamma_1^c$  and  $\gamma_2^c$ .

Figure 2 illustrates the result of the second comparative static exercise, viz, the effect of changes in  $(\delta_2/\delta_1)$ . An increase in the importance of management relative to labor effort (i.e., a decrease in  $(\delta_2/\delta_1)$ ) lowers  $\gamma_1^c$  and increases  $\gamma_2^c$ . In other words, the area covered by the fixed wage contract in Figure 1 increases, while that covered by the fixed rental contract shrinks. Precisely the opposite would be true if the importance of labor effort increases relative to management. This result, which is eminently in accord with intuition, explains the transformation of share contracts into wage contracts in India in response to the introduction of the High Yielding Variety (HYV) technology. The increased importance of know-how in production caused a decrease in  $(\delta_2/\delta_1)$  changing sharecropping to fixed wage contracts. By the same reasoning it also follows that if the initial situation were one predominantly of fixed rental contracts, a sufficiently large

FIGURE 2. DEPENDENCE OF CRITICAL RELATIVE EFFICIENCY PARAMETERS ON  $(\delta_2/\delta_1)$

(Parameter values:  $\delta_1 + \delta_2 = 0.7$ ,  $\delta_3 = \delta_4 = 0.15$ ,  $\epsilon = 0.5$ ,  $A = 3$ ,  $p = w = 1.0$ ,  $u = v = 1.25$ .)

decline in  $(\delta_2/\delta_1)$  could result in a direct transition to a regime of fixed wage contracts, bypassing the share contract altogether. Over time, the diffusion of know-how reduces the advantage possessed by the landlord (i.e.,  $\gamma_2$  increases), and we might observe a reappearance of share contracts. Ranjit Sau (1976) reports some such cases in Haryana (India) ten to twelve years after HYV technology was first introduced in the area.

Figure 2 also explains an observation made by Reid (1979) that in the U.S. South there was a strong correlation between the extent of sharecropping and the labor intensity of production. Cotton, for example, which is a highly labor-intensive crop, was typically cultivated under sharecropping arrangements. The more labor intensive the crop, the greater the premium placed on supervision and, therefore, the less likely are the landlords to self-cultivate. This, together with the poor management abilities of the recently freed slaves (which made fixed rental tenancies unlikely), resulted in sharecropping as the dominant contractual arrangement.

Figure 3 demonstrates that  $\gamma_1^c$  increases and  $\gamma_2^c$  declines as the importance of supervision increases (i.e., as  $\epsilon$  increases). This is because as the activity in which the tenant has the advantage (supervision) acquires greater importance in the production process, some fixed wage contracts that previ-

FIGURE 3. DEPENDENCE OF CRITICAL RELATIVE EFFICIENCY PARAMETERS ON  $\epsilon$

(Parameter values:  $\delta_1 = 0$ ,  $\delta_2 = 0.4$ ,  $\delta_3 = \delta_4 = 0.2$ ,  $A = 4$ ,  $p = w = 1$ ,  $u = v = 1.25$ .)

FIGURE 4. DEPENDENCE OF CRITICAL RELATIVE EFFICIENCY PARAMETERS ON RATIO OF OPPORTUNITY INCOMES

(Parameter values:  $\delta_1 = 0.2$ ,  $\delta_2 = 0.4$ ,  $\delta_3 = \delta_4 = 0.2$ ,  $\epsilon = 0.5$ ,  $A = 3$ ,  $p = w = 0.6$ ,  $u = 1.2$ .)

ously marginally dominated sharecropping would now give way to share contracts. Likewise, some share contracts that previously dominated fixed rental contracts would now give way to the latter.

The importance of labor monitoring depends on the variance of the quality of effort allowed by the production technology. Specialization of labor facilitates labor monitoring (i.e., reduces  $\epsilon$ ) through routinization and systematization of labor tasks. Often mechanization of activities implies that the pace and quality of output are primarily determined by machine specifications rather than by the quality of the operator's effort, thus reducing the importance of labor supervision (i.e., reducing  $\epsilon$ ); the machine supervises labor.<sup>19</sup> Thus, following a technological change involving either labor specialization or mechanization, we would expect to see a reduction in the supervision requirement (i.e., lower  $\epsilon$ ) and consequently a change from share and fixed rental contracts toward wage contracts. We thus have an additional explanation for the shift toward wage contracts

in Punjab (India) in the mid-1960's, since the introduction of the HYV technology was accompanied by mechanization. It is, therefore, important to consider the possible supervision consequences of labor displacing mechanization.

Figure 4 describes the impact of a change in the opportunity incomes on the contractual structure. An increase in the opportunity income of the landlord, *ceteris paribus*, decreases the area in  $(\gamma_1, \gamma_2)$  space corresponding to fixed wage contracts, while increasing that corresponding to fixed rental contracts (i.e.,  $\gamma_1^c$  increases and  $\gamma_2^c$  decreases). An implication of this result is that geographical areas in which the opportunity incomes of landlords are relative higher, *ceteris paribus*, are likely to exhibit a greater prevalence of fixed rental tenancy. Shigemochi Hirashima (1978, p. 56) has suggested that, in Pakistan, wage contracts became less prevalent as the supply of agricultural labor (as a percentage of total rural population engaged in cultivation) increased during the period 1901–31. This observation could be explained by the result presented in Figure 4; the increase in the percentage of agricultural laborers would *ceteris paribus* result in an increase in  $v/u$  and consequently an increase in  $\gamma_1^c$ .

<sup>19</sup>Alston (1978) offers convincing arguments as to why mechanization might reduce supervision requirements.

FIGURE 5. EFFECT OF  $(\delta_2/\delta_1)$  ON THE PROFIT SHARE

(Parameter values:  $\delta_1 + \delta_2 = 0.7$ ,  $\delta_3 = \delta_4 = 0.15$ ,  $\epsilon = 0.5$ ,  $A = p = w = 1$ ,  $u = v = 1.25$ ,  $\gamma_1 = \gamma_2 = 0.4$ )

FIGURE 6. EFFECT OF  $\epsilon$  ON THE PROFIT SHARE

(Parameter values:  $\delta_1 = 0.2$ ,  $\delta_2 = 0.4$ ,  $\delta_3 = \delta_4 = 0.2$ ,  $A = 4$ ,  $p = w = 1$ ,  $u = v = 1.25$ ,  $\gamma_1 = \gamma_2 = 0.4$ )

H. Laxminarayan and S. Tyagi (1977) while discussing the interstate variation in tenancy in India based on the NSS data (1970–71) and the Agricultural Census (1971–72) make an observation similar to the one made by Hirashima.

Suppose that the industrialization strategy pursued by a developing country is such that the demand for people with greater human capital endowment is created at a faster rate than for unskilled workers, without a corresponding change in the supply. To the extent that the members of landlords' families are likely to have had a greater opportunity to acquire human capital, a consequence of such industrialization would be an increase in  $v$ , but not in  $u$ . Figure 4 suggests that in the face of a steady increase in  $(v/u)$ , we would expect to see a transition from fixed wage contracts to sharecropping; a further increase in  $(v/u)$  would result in a transition from sharecropping to fixed rental contracts with absentee landownership. On the other hand, in instances where  $(v/u)$  decreases, there would be a shift towards wage contracts. Taiwan may be cited as one such case.

A persistent puzzle in the sharecropping literature is why the share,  $\beta$ , is often observed to be in the vicinity of one-half; it rarely, if ever, takes on values at either extreme of its range. Figures 5 and 6 offer a possible explanation. Figure 5 depicts the endogenized value of  $\beta$  when  $(\delta_2/\delta_1)$  is

varied keeping all else constant, and Figure 6 shows the endogenized  $\beta$  as a function of  $\epsilon$ . The entire range of  $\beta^*$  indicated in the figures will, however, not necessarily be observed when  $(\delta_1/\delta_2)$  and  $\epsilon$  are varied. When we also allow for fixed wage and fixed rental contracts, sharecropping may not be the dominant contract. The shares in the range where the share contract is the dominant one are represented by the solid portions of the curves in Figures 5 and 6; the dashed portions represent situations where sharecropping is dominated, although  $\beta$  is optimally chosen. Thus only the solid segments of these curves represent *realizable* shares, since outside this range sharecropping will not be observed.

From these figures we see that the variation in the realizable (and thus observable) values of  $\beta^*$  around one-half is minimal, despite the relatively large polarization assumed in the abilities of the landlords and tenants ( $\gamma_1 = \gamma_2 = 0.4$ ). While the bounds on the observable values of  $\beta$  depend on the specific parameter values chosen, these results shed some light on why the share is found to be in the vicinity of one-half. A large deviation of the share from one-half would exacerbate the disincentive effect by diluting incentives for either the tenant or the landlord, which would result in share-

cropping being dominated by either the fixed wage or the fixed rental contract. Thus when sharecropping is the observable outcome, the share is neither inordinately high nor inordinately low.<sup>20</sup> We are in agreement with Bliss and Stern in that the choice of the share is probably rooted in tradition and one-half has the appeal of equity. Any attempt to explain why it must be exactly one-half is bound to be contrived, besides being empirically false. What the above results indicate is that middling values of the share are consistent not only with equity considerations, but also with efficiency requirements.

### III. Summary and Conclusions

In this paper we have formally modeled the idea that each contractual form entails a different type of agent (landlord or tenant) providing unmarketed factor inputs. Sharecropping is viewed as a partnership in which each partner provides the unmarketed factor input in which he is the better endowed. The contractual structure has been endogenized by solving the problem of optimal time allocation in cultivation by each agent in terms of exogenous parameters such as the opportunity incomes, characteristics of the prevailing technology, and attributes of the economic agents. The model has then been applied to explain some variations over time in the contractual structure in India and the United States.

Our view that sharecropping is a partnership is consistent with three significant empirical observations made in the literature. First, the yields on farms cultivated under sharecropping are sometimes found to be higher than on farms alternatively cultivated, despite the moral hazard inherent in the noncooperative nature of the share contract. In our model this may result from the advantage of being able to pool unmarketed resources. Second, the hypothesis that the greater the production risk, the greater the

prevalence of sharecropping, has received little support in recent empirical investigations (Rao, 1971; Pant, 1981). These studies cast some doubt on the alternative hypothesis that risk sharing is the principal motivation behind sharecropping. Third, the relative insensitivity of the share  $\beta$  to the variation in technology and market characteristics across different regions has also been shown to be consistent with our model.

It should be pointed out that although "management" and "supervision" are the two unmarketed resources relevant to the specific cases we have tried to explain, the model could be cast in terms of *any* unmarketed resources. What is crucial to the model is that there be no markets in which the contract-determining resources can be traded independently of the time of the resource owner. We do not analyze in this paper the interesting question as to why markets might not exist for certain resources.

Our model implies that in sharecropping arrangements, landlords contribute some unmarketed resource, while in fixed rental arrangements they do not. In reality, one would expect some landlord participation—though to a smaller extent—even in fixed rental arrangements due to long-run considerations (such as the maintenance of soil productivity, etc.). Reid (1979, p. 295) has presented evidence that, in the U.S. post-bellum South, landlord participation was greater in share contracts than in fixed rent contracts. Bliss and Stern (p. 127) and Thomas Smith (1959, pp. 153–55) present similar evidence on contracts in India and Japan, respectively. We have demonstrated that the implications of our theory are consistent with observations drawn from a diverse set of countries and time periods. The prevalence of the metayage system in continental Europe in the eighteenth and nineteenth centuries and of share contracts in the present day U.S. Midwest may, however, prove to be anomalies for our theory.

The assumption of only two classes and a single production function inevitably leads to a single dominant contract. The model can, however, be extended to incorporate a heterogeneous rural population with more than two classes or more than one produc-

<sup>20</sup> It should be noted that although we have cast the problem in terms of profit shares, the observations made in the literature usually refer to crop shares. This intuition is, however, equally valid for crop shares.

tion function (for example, different crops in the same area), or both. It is easy to see that such an extension could explain the coexistence of different contracts in the same area and would also be consistent with "the agricultural ladder" hypothesis.<sup>21</sup>

Our model assumes that tenants are landless. This assumption could be dropped at the cost of a minor increase in computational difficulty. Such a modification would allow us to explain the puzzling reversal of the traditional picture of a poor tenant and a rich landowner. It has been observed that sometimes rich farmers armed with managerial ability and farm machinery (i.e., low  $\epsilon$ , and low  $\delta_2/\delta_1$ ) might want to lease land from poor landowners at a fixed rental (Nripen Bandyopadhyay, 1975; M. Nadkarni, 1976). The fixed rental tenants engaged in tobacco cultivation cited by Rao (1971) also belong to this category. The motivation, of course, is to adjust the operational holdings to match their high resource endowment.

We have followed the literature in modeling sharecropping as a one-period noncooperative game. We believe, however, that typically tenancy relationships are of a long-run nature. In addition, there are many implicit instruments (for example, consumption credit) through which the landlord may exercise control over the tenant to approximate the cooperative outcome. The exercise we have performed in this paper can be repeated under the assumption of a cooperative game.

The analysis of institutional arrangements presented here may have interesting implications for the study of similar arrangements in industrialized countries. The institutions of sharecropping and fixed rental tenancy resemble, for example, the revenue-sharing and royalty-charging franchise arrangements common in the American service sector as suggested by Peter Murrell. Similarly the technology transfers across national boundaries involve tenancy-like arrangements, for example, entirely owned subsidiaries by multinationals (wage contracts), joint ventures between multinationals and domestic

firms (share contracts), and royalty-charging arrangements (fixed rentals). Analysis similar to that employed in this paper could be used to study these arrangements.

#### APPENDIX

For the Cobb-Douglas specifications (15) and (16) the function  $f$  in (3) of a farm takes the form:

$$(A1) \quad f(t, s, M, L, H; \epsilon) = At^{a_1}M^{a_2}s^{a_3}L^{a_4}H^{a_5},$$

where

$$(A2) \quad a_1 = \delta_1, \quad a_2 = \delta_2, \quad a_3 = \epsilon\delta_3, \\ a_4 = (1 - \epsilon)\delta_3, \quad a_5 = \delta_4,$$

with

$$(A3) \quad \sum_{i=1}^5 a_i = 1.$$

A straightforward maximization reduces the restricted profit function (8) to the form

$$(A4) \quad \Pi(t, s) = Dt^{b_1}s^{b_2},$$

where

$$(A5) \quad b_1 = a_1/c, \quad b_2 = a_3/c, \quad c = 1 - a_2 - a_4,$$

$$(A6) \quad D = PAH^{a_5}\bar{M}^{a_2}\bar{L}^{a_4} - p\bar{M} - w\bar{L},$$

with

$$(A7a) \quad \bar{M} = \left[ PAH^{a_5} \frac{a_2}{p} \left( \frac{a_4 p}{a_2 w} \right)^{a_4} \right]^{1/c},$$

$$(A7b) \quad \bar{L} = \left[ PAH^{a_5} \frac{a_4}{w} \left( \frac{a_2 w}{a_4 p} \right)^{a_2} \right]^{1/c}.$$

1. *Fixed Wage Contract.* The landlord's expected profit  $\Pi_1^w$  is

$$(A8) \quad \max_{t_1, s_1} D^w t_1^{b_1} s_1^{b_2} + v(1 - t_1 - s_1)$$

$$0 \leq t_1 \leq 1, 0 \leq s_1 \leq 1, 0 \leq t_1 + s_1 \leq 1,$$

<sup>21</sup>For a summary description of the hypothesis, see Reid (1977, p. 405; and 1979, p. 300).

where  $D^{fw}$  is obtained from  $D$  by replacing  $A$  by  $A\gamma_1^{a_3}$  in (A7a), (A7b), and (A6).

Defining  $d = 1 - b_1 - b_2$ , the solution to (A8) is given by

$$(A9a) \quad t_1 = \left[ D^{fw} \frac{b_1}{v} \left( \frac{b_2}{b_1} \right)^{b_2} \right]^{1/d}; \quad s_1 = \frac{b_2}{b_1} t_1,$$

when  $t_1 + s_1 < 1$ , and

$$(A9b) \quad t_1 = \frac{b_1}{b_1 + b_2}; \quad s_1 = \frac{b_2}{b_1 + b_2}$$

otherwise.

2. *Fixed Rental Contract.* The tenant's expected profit,  $\Pi_2^f$ , prior to paying the rental is given by

$$(A10) \quad \max_{t_2, s_2} D^{fr} t_2^{b_1} s_2^{b_2} + u(1 - t_2 - s_2)$$

$$0 \leq t_2 \leq 1, 0 \leq s_2 \leq 1, 0 \leq t_2 + s_2 \leq 1,$$

where  $D^{fr}$  is obtained from  $D$  by replacing  $A$  by  $A\gamma_1^{a_1}$  in (A7a), (A7b), and (A6).

The solution to (A10) is given by

$$(A11) \quad t_2 = \left[ D^{fr} \frac{b_1}{v} \left( \frac{b_2}{b_1} \right)^{b_2} \right]^{1/d}; \quad s_2 = \frac{b_2}{b_1} t_2,$$

when  $t_2 + s_2 < 1$ , and (A9b) holds.

The landlord's expected payoff is then

$$(A12) \quad \Pi_1^f = \max[\Pi_2^f - u, 0] + v.$$

3. *Share Contract.* The reaction function of the tenant, which is the solution to (10), is given by

$$(A13) \quad s_2 = \min \left\{ 1, \left[ \frac{b_2 \beta D}{u} t_1^{b_1} \right]^{1/(1-b_2)} \right\}.$$

The landlord's reaction function, which is the solution to (11), is given by

$$(A14) \quad t_1 = \min \left\{ 1, \left[ \frac{b_1(1-\beta)Ds_2^{b_2}}{v} \right]^{1/(1-b_1)} \right\}.$$

Assuming an interior solution, the Nash equilibrium for given  $\beta$  is obtained as

$$(A15a) \quad t_1^*(\beta) = \left[ \frac{b_1 D}{v} \left( \frac{b_2 v}{b_1 u} \right)^{b_2} \right]^{1/d}$$

$$\times [\beta^{b_2} (1-\beta)^{1-b_2}]^{1/d},$$

$$(A15b) \quad s_2^*(\beta) = \left[ \frac{b_1 D}{v} \left( \frac{b_2 v}{b_1 u} \right)^{1-b_1} \right]^{1/d}$$

$$\times [\beta^{1-b_1} (1-\beta)^{b_1}]^{1/d}.$$

Finally, the landlord chooses  $\beta$ , as in (12), by solving

$$(A17) \quad \max_{\beta} D t_1^{*b_1}(\beta) s_2^{*b_2}(\beta)$$

$$+ v[1 - t_1^*(\beta)] - u s_2^*(\beta).$$

# Oil Field Unitization: Contractual Failure in the Presence of Imperfect Information

By STEVEN N. WIGGINS AND GARY D. LIBECAP\*

Private contracting is a solution to problems of production and exchange when transactions costs are low, but if they are high, contracting may be less successful (Ronald Coase, 1960; Oliver Williamson, 1976; Victor Goldberg, 1976). Accordingly, incorporation of transactions costs into economic analysis is necessary to determine when private contracting will be effective and when it will not. There has been, however, little empirical analysis, based upon testable theories, of the impact of transactions costs on contracting. This paper presents such an analysis, and shows that imperfect information can seriously limit the effectiveness of private contracting. The case considered is the widespread failure of private crude oil producing firms to unitize U.S. oil fields to reduce rent dissipation. Rent dissipation follows as multiple firms compete for migratory oil in common oil pools. Competitive production leads to excessive wells and surface storage, higher extraction costs because subsurface pressures are inefficiently depleted, and reduced overall oil recovery. Unitization is the obvious private contractual solution to rent dissipation. Under

unitization a single firm is selected to develop the reservoir with net returns shared by all parties, including firms that would otherwise be producing. As early as 1916, the U.S. Bureau of Mines called for unitization of U.S. oil fields; yet, by 1947, Joe Bain found only 12 fully unitized fields out of some 3,000 U.S. fields sampled (p. 29).<sup>1</sup> Our forthcoming paper (1985) shows that as late as 1975 neither Oklahoma nor Texas, two leading producing states, had as much as 40 percent of production from field-wide units.

We argue that the principal causes of contractual failure are imperfect and asymmetric information that prevent agreement on lease values and hold-out strategies of firms to increase their share of unit rents.<sup>2</sup> This study is based on an empirical analysis of unitization contracting in seven oil fields. Our data are from trade journals and company records, including detailed engineering studies, estimates of parameters affecting lease values, unit share allocation formulas, and votes on shares. Besides these quantitative data, the company files include minutes of negotiations on bargaining strategy and let-

We thank Ray Battalio, Victor Goldberg, Jim Griffin, Jan Kmenta, James Smith, Oliver Williamson, and the referees for helpful comments. We also thank participants in university seminars at Arizona, Duke, Houston, the Saarlands, Texas A&M, Washington, and Yale. Capable research assistance was provided by Phil Mizzi. Funding from the NSF under grant SES-8207826 and the Center for Energy and Mineral Resources at Texas A&M is gratefully acknowledged. The order of names is random. Finally, we acknowledge our debt to the late Bruce A. Landis, Jr., a widely recognized unitization expert, whose aid in our gaining access to negotiation records made this research possible.

<sup>1</sup>In 1914, the U.S. Bureau of Mines estimated annual losses from competitive extraction at \$50 million, approximately one-quarter of the total value of U.S. production. In 1924, the Federal Oil Conservation Board was organized to review wasteful oil extraction, and it specifically endorsed unitization.

<sup>2</sup>Stephen McDonald (1979, p. 137) and others have pointed to hold-out strategies by firms for increased shares of unitized rents which block agreement. Our analysis reveals that this explanation is incomplete. A simple hold-out strategy could be employed by any firm, and it would be unrelated to structural advantage or the stage of field development. Yet, we find there are systematic differences, based upon structural conditions, across firms in the willingness of firms to join units. Further, we find that unitization contracts can be successfully completed late, as fields near depletion, or very early before production heterogeneities among firms are known.

ters regarding votes, lease parameters, and estimated gains from agreement.<sup>3</sup> From this unusually rich data source we construct a detailed analysis of negotiations on the seven fields and isolate the causes of contractual failure. Section I outlines the general contracting problem. Section II develops a simple theory of contracting in the presence of imperfect information, and Section III provides the empirical analysis.

## I. The Contracting Problem

### A. Contracting in General

Coase, Goldberg, Williamson, and others have argued that transactions costs can seriously disrupt private contracting. Goldberg and Williamson, for example, explore cases where *ex post* information asymmetries cause contracting to fail when complete contingent claims contracts cannot be written. Contingent updates are difficult to incorporate when new information does not arrive symmetrically across agents. Coase examines a different case where large numbers of parties prevent contracts from being written. In this paper we explore a third and potentially more important cause of contractual failure, *ex ante* information problems that occur during contract negotiation. In unitization contracting there are only a small number of firms involved, typically fewer than 15, so that large numbers problems frequently associated with transactions costs are not encountered. Further, firms do not rely on later events to reveal more accurate information to update contracts. Instead, the unitization bargaining problem occurs before contract execution and centers on the establishment of once-and-for-all unit shares. Dispute focuses on differences in lease value estimates, since lease values determine unit shares. Differences in value estimates arise because of general uncertainty regarding res-

ervoir dynamics and information asymmetries among the bargaining parties. Those disputes block consensus on unit shares, and contribute to contractual failure.

The structural characteristics that lead to contractual failure in unitization are also present in many other contracting contexts. In unitization, bargaining disputes regarding the relative values of leases to be included in the unit lead to a breakdown of negotiations for a sharing formula. It is clear that these same factors are common in other settings, where it is asserted that contracting will provide an efficient, low-cost solution to problems of allocation and exchange. A conceptually similar problem is contracting between firms and workers in team production, when monitoring is imperfect (Richard Startz, 1983). Another related case is private contracting between consumers and firms to reduce pollution. In both cases it is difficult to determine the *ex ante* contribution of each party to production, and, if successful, the contract changes the nature of production so that *ex post* adjustments are not generally feasible. These cases suggest that empirically untested optimism regarding the power of private contracting in the presence of imperfect information may be unwarranted and that more systematic analysis is needed.

### B. Contracting for Unitization

Unitization raises field rents by increasing oil recovery and reducing production costs compared to common pool production. Common pool conditions arise as multiple firms extract oil from the same reservoir. Land owners grant firms access to the reservoir through leases, and fragmented land ownership results in numerous firms exploiting the pool. Each is motivated to competitively drill and extract oil. Within the reservoir, oil is migratory, and property rights to it are assigned only upon extraction. Rapid production by a firm lowers subsurface pressure around its wells, stimulating oil immigration, which increases its share of total output. In the aggregate, these production strategies raise marginal extraction costs and reduce total recovery. High extraction rates deplete natural gas throughout the field, making oil

<sup>3</sup>The company records are from one of the largest producing firms in the United States. We were granted access to their unitization files. For reasons of confidentiality we cannot reveal the names of the bargaining firms on the seven fields examined in the paper.

more viscous and forcing costly artificial lift and injection of natural gas and water to raise pressure. Further, as natural gas leaves solution, pockets of oil become permanently trapped. With unitization these problems can be mitigated by having only a single firm develop the field with net revenues shared by all firms.

The division of net revenues is the central issue in unitization negotiations. The sharing formula is specified at unit agreement, and it assigns *once-and-for-all* shares of unit rents. A permanent share assignment is required because reservoir dynamics and relative lease production potential are fundamentally altered under unitization. Under unit management some wells are plugged and others are converted to gas injection to maintain pressure. No direct production occurs from these leases, and the oil originally below them is extracted elsewhere. Further, widespread injection of natural gas and water increases pressure in certain parts of the field, altering oil migration patterns. Because of these technical changes in the dynamics of production, unit shares must be based on *pre-unitization* estimates of lease values, and share negotiations cannot be reopened later to adjust for new contingencies.

Unit shares are based on estimates of lease values, but general uncertainty and asymmetric information block consensus on value estimates and, hence, shares. The parameters influencing lease values and unit shares include current and cumulative oil and gas production, number of wells, surface acreage, bottom hole pressure, gross acre feet of pay (volume of the producing formation), net acre feet of pay (nonporous and non-oil-bearing rock is subtracted from the gross measure), and remaining reserves (original oil-in-place less cumulative production). The first four parameters are directly observable and uncontroversial. The last four parameters describe reservoir characteristics under each lease, and provide more complete information on lease potentials. These are estimated from well logs and production histories, and require highly subjective interpretation by geologists and engineers. The need for subjective interpretation using arbitrary procedures leads to serious disputes. For ex-

ample, it was noted during negotiations in the Western RKM unit in Texas that: "The Engineering Committee could not agree upon oil reserves for a large number of tracts in the unit area because of the poor quality and interpretive nature of the available basic data" (Letter, Western RKM Unit File, Company Records).

The information problems that limit the number of parameters that can be used in allocation formulas is further illustrated in the calculation of remaining primary oil reserves. This parameter is a principal component of nonunitized lease value because it is an estimate of oil that may be produced from the lease under competitive production. It establishes a benchmark against which the value offered under unitization can be evaluated. Yet, remaining primary reserves are estimated using simple ordinary least square (*OLS*) regressions on specific functional forms that are often inaccurate. For example, in unsuccessful unit negotiations on the Wasson field in 1971, ultimate primary recovery (cumulative production plus remaining primary reserves) was estimated at 48 million barrels. This was based on production decline curves inferred from a production history of 36 million barrels; thus, it was estimated that one-quarter of the field's primary reserves remained. In 1978 negotiations were reopened after 2 million additional barrels had been produced. Ultimate primary was reestimated at 43 million barrels. A 6 percent change in output led to new information and a revision of remaining reserves estimates by approximately 50 percent (Wasson Unit File, Company Records).

Because of the subjective nature and wide variation in estimates of subsurface parameters, negotiating parties rely upon a small set of objectively measurable variables, but they are likely to be poor indicators of lease value. The problem is illustrated in Table 1 with regression estimates of output per acre using objective parameters for leases on three fields. Output per acre is a key determinant of lease value. In all three fields there remains a large, unexplained residual variance in the estimates due to inherent variation in reservoir quality and differences in the stage of development among leases that are not re-

TABLE 1—REGRESSIONS OF OUTPUT PER ACRE<sup>a</sup>

	Independent Variables:			Statistics		
	Intercept	Cumulative Output/Acre	Wells/Acre	Mean	SER	Coefficient
Goldsmith/Landreth	28.23 (9.79)	.036 (.0063)	38.87 (196.46)	68	46	68
North Cowden	40.19 (35.19)	.0083 (.0012)	618.69 (1471.58)	85	33	39
Prentice Northeast	2.45 (11.15)	.045 (.0062)	2602.88 (911.15)	116	39	34

<sup>a</sup>Dependent variable: Output per acre; standard errors are shown in parentheses.

flected in measurable parameters. For example, mean output per acre on Goldsmith/Landreth is 68 barrels with a standard error of the regression (*SER*) of 46 barrels. Similarly on North Cowden mean output is 85 barrels with *SER* 33, and on Prentice mean output is 116 barrels with *SER* 39. With so much unexplained variation in lease productivity there are ample grounds for disagreement about how long production differences will persist and whether they will grow larger or smaller over time. It is important to note that in such disputes the subjective judgment of a firm's engineers, who are familiar with individual well performance, provides an important source of *private* information about lease values. These judgements, however, are not easily verified by other parties, and accordingly, are difficult to incorporate into the unit allocation formula.

The problems of estimation and extrapolation for static structural characteristics are compounded in the estimation of dynamic reservoir performance characteristics, which are central to the negotiation of relative unit shares. Efforts to predict future performance are typically *ad hoc*. For example, predicted future production is often a simple extrapolation of past production with little systematic account taken of the pattern of water encroachment or other key variables. Such predictions are sensitive to the specific functional forms chosen. Companies often have differing, and strong, opinions about the correct estimation procedure, when choices may reallocate millions of dollars, and there is no generally accepted standard. The result is that consensus cannot be achieved on future

lease output. Such an agreement, however, is necessary for successful unit share negotiations.

These problems are particularly important for highly productive leases that are constrained by prorationing output quotas under state regulation. To estimate the well's future producing capability, it is necessary to have observations of the rate of production decline, which varies substantially across leases. On highly productive leases, producing the maximum regulated allowable, however, such observations are not available. Hence, the data at which the decline will begin and its rate must be based on the subjective opinions of engineers and geologists, which are open to dispute. Below we review cases where such problems impede unit agreements because parties cannot agree on potential future production. These information problems are central to the failure of private contracting.<sup>4</sup> We now develop a formal theory for analyzing unitization contracting.

<sup>4</sup>The unitization contracting problem is summarized by Raymond Myers:

The principal obstacle to full, voluntary agreement is the problem of dividing the proceeds of production. If development of the area sought to be unitized is complete, ... some lessors and leases may be inclined to rely on the possibility that... the entire production from their land will be more valuable than an undivided interest in production from a much larger unit. If development of the pool is relatively complete, there is frequent acrimony as to the respective shares of production to be given owners of interest in favorable parts of the structure and owners of interests in less favorable areas.... [1967, p. 108]

## II. Theory: Contracting for Unitization Agreements

This section presents a simple, testable model of a firm's decision to join a unit. The decision is made so as to maximize the expected present value of the firm's lease(s). There are two central features of assessing the relative values of oil leases that lead to contractual failure. One feature is that each firm has access to better information concerning the highly uncertain value of its own leases than do other firms in the field. It is assumed that at least a portion of this private information cannot be successfully communicated.<sup>5</sup> A second key aspect is that firms differ regarding the transformation of raw data into value estimates, and there is no absolute standard that can resolve differences. Either of these information problems is sufficient to cause the observed contractual breakdown, and both appear to be empirically important.

Let the raw, publicly available information concerning lease  $i$  be a vector of random variables  $x_i$  and the privately available information be random variables  $z_i$ . Firms have the incentives to develop procedures to share information. As discussed above, however, it is unlikely that these mechanisms will be perfect in equilibrium and so we assume that  $z_i$  is not empty. Finally, let respective maps to value estimates be the functions  $g$  and  $h$ :

$$(1) \quad \hat{V}_p^i = g(x_i);$$

$$(2) \quad \hat{V}_f^i = h(x_i, z_i),$$

where  $\hat{V}_p^i$  and  $\hat{V}_f^i$  are random variables that correspond to the public and private estimates of the value of lease  $i$ . The simple

form taken by (1) and (2) belies the potential complexity of the process under consideration. For example, the vector  $x_i$  contains objective data on production and information each firm reveals about the characteristics of its leases. Accordingly, misrepresentations concerning lease characteristics are also included in the  $x_i$ , though they may be completely discounted and not affect  $\hat{V}_p^i$ . Similarly, if firms truthfully reveal a characteristic, but it is not believed because it cannot be verified, that information also will not affect  $\hat{V}_p^i$ , but it will affect  $\hat{V}_f^i$ . On the other hand, if firms lie regarding lease characteristic  $j$ , and the lies are believed, then  $z_j^i$  will be the difference between the true value of the characteristic and the value  $x_j^i$  believed to be true by other parties. In this case the misrepresentations clearly influence  $\hat{V}_p^i$ . A related case is if firms truthfully reveal only favorable information, then  $z_i$  consists of the unfavorable information held back;  $x_i$  will not include unfavorable data available only from the firm, if the firm cannot be induced to reveal it. There are also other possibilities. Hence, while (1) and (2) take a simple form they admit the full range of value estimation problems due to asymmetric information. It is convenient to assume, for now, that both information sources are unbiased:

$$(3) \quad E(\hat{V}_p^i) = E(\hat{V}_f^i) = V_i,$$

where  $V_i$  is true lease value and  $E(\cdot)$  is the mathematical expected value. In principal, of course, either or both estimation procedures may be biased as discussed above. The simplifying assumption in (3) is that the estimation rule, (1), can correct for these potential biases. This assumption is made solely to illustrate that contracting conflicts can occur even when actors have rational expectations with respect to lease values. As it turns out, this assumption can be relaxed easily, but this would only complicate the exposition while adding little additional insight. Conflict over estimated lease values and unit shares is the heart of the contracting problem analyzed below, and it is not critical whether the conflict is due to inherent uncertainty about values or because of unrecognized biases in the estimation of lease values.

<sup>5</sup> The exact amount of information that can be communicated is a complex theoretical problem. Since firms have an incentive to selectively reveal only favorable information about the value of their leases, there will be some degree of imperfection in communication. Moreover, as described in the text, lease values estimates are influenced by firm-specific management policies, the details of which are difficult to reliably convey to other firms.

Finally we assume that unit shares will be based upon public estimates of lease values:

$$(4) \quad S_i = \hat{V}_p^i / V^*.$$

where  $V^* = \sum \hat{V}_p^i$ . This assumption is not central to the analysis and is used only to close the model.<sup>6</sup> Any alternative assumption regarding share assignment will yield the same qualitative results for the analysis so long as public value estimates influence final share assignments.<sup>7</sup> We will refer to (4) as the allocation rule. Given that the allocation rule will be the one offered the firm in unit negotiation, we can now characterize firms' decisions to join the unit.

The firm's objective in considering whether to join is to maximize the expected present value of its leases with respect to the date it joins the unit,  $t_u$ , and it may choose never to join. Formally, we have

$$(5) \quad \text{Max}_{t_u} E_f(PV_i) \\ = E_f \left\{ \int_{t_0}^{t_u} \pi_n(t) s_n^i(t) e^{-rt} dt \right. \\ \left. + \int_{t_u}^T \pi_u(t_u, t) s_u^i(t_u) e^{-rt} dt \right\},$$

where  $PV_i$  = the present value of lease  $i$ ,  $t_u$  = the time the lease is put in the unit,  $\pi_n$  = the stream of nonunitized net revenues from the field,  $s_n^i$  = lease  $i$ 's share of non-unitized net revenues,  $\pi_u$  = the stream of unitized net revenues from the field,  $s_u^i$  =

lease  $i$ 's share of unitized production,  $T$  = field life,  $r$  = the common discount rate for all firms, and  $E_f(\cdot)$  represents the firm's expectations. Differentiating (5) with respect to  $t_u$ , we derive the necessary first-order condition for the firm to join the unit at a particular time:

$$(6) \quad E_f \left\{ \left[ \pi_n(t) s_n^i(t) - \pi_u(t) s_u^i(t_u) \right] e^{-rt} \right. \\ \left. + \int_{t_u}^T \left[ \frac{\partial \pi_u(t_u, t)}{\partial t_u} s_u^i(t_u) \right. \right. \\ \left. \left. + \pi_u(t_u, t) \frac{\partial s_u^i}{\partial t_u} \right] e^{-rt} dt \right\} = 0.$$

Rewriting (6) we have

$$(7) \quad E_f(\alpha_i + \eta l_i) = E_f(\beta_i - s_i \lambda_i),$$

where  $\alpha_i = \pi_n(t) s_n^i(t) e^{-rt}$ ,

$$\beta_i = \pi_u(t) s_u^i(t_u) e^{-rt}, \quad l_i = \partial s_u^i / \partial t_u,$$

$$\eta = \int_{t_u}^T \pi_u(t_u, t) e^{-rt} dt, \quad s_i = s_u^i(t_u),$$

$$\lambda_i = \int_{t_u}^T \frac{\partial \pi_u(t_u, t)}{\partial t_u} e^{-rt} dt < 0.$$

The separation of  $l_i$  from the integral is appropriate since shares are fixed at the time of unitization.  $\alpha_i$  represents the firm's instantaneous nonunitized net revenues, and  $\eta l_i$  represents the gain in unitized share the firm expects to receive if there is delay in unit formation.  $\beta_i$  represents the firm's instantaneous share of unitized net revenues, and  $\lambda_i$  represents the firm's share of lowered field rents caused by delayed unitization.

Since  $\sum_i l_i = 0$  and  $\sum \alpha_i \leq \sum \beta_i - \sum l_i$ , there are aggregate incentives to unitize, but the division of the increased rents determines whether or not an individual firm will have incentive to join. Before considering reasons why, according to the model, certain firms will delay joining, let us rule out some other reasons for delay that are inconsistent with the model. Suppose the sharing rule is the number of wells, then the firm will not delay

<sup>6</sup>Given (4), the economic content of (3) follows without loss of generality. Since  $\sum S_i = 1$  by construction, the average share must be unbiased. Selective revelation or distortion of facts, then, is a zero sum game that can only increase the variance in the assigned shares about the true "fair" shares, i.e., those that would be assigned if  $V_i$  rather than  $\hat{V}_p^i$  were in the numerator of (4). Hence, if (3) fails, and the estimates are biased, rather than using the terminology "variance" below, "Mean Squared Error" should be substituted and similarly for higher moments, but otherwise the analysis is unchanged.

<sup>7</sup>For example, if unit shares in equilibrium were an increasing but strictly concave function of  $\hat{V}_p^i$ , because small firms can force concessions from large firms, the analysis below still applies.

unit formation merely to drill more wells absent disagreement over the number of wells it *can* drill. If all parties agree on the number of wells that can be drilled on a lease and if there is no desire to change the way in which wells enter the allocation rule, then the potential number of wells will enter  $\hat{V}_f^i$  and  $\hat{V}_p^i$  in precisely the same way, and there will be no need to delay unitization until the wells are actually drilled. Similar reasoning applies to any other strategic advantage of one party; so long as other parties recognize the valuation consequences of the advantage, it becomes immediately incorporated into the allocation rule, and delay is unnecessary.

There are other reasons, however, why the left-hand side of (7) may be greater than the right, in which case the model predicts that the firm will prefer to delay unit formation. A firm may wish to delay unit formation if its private value estimates exceed public value estimates,  $\hat{V}_f^i > \hat{V}_p^i$ , and if the firm expects the public estimate to be revised upward as more information on lease value becomes available. Differences between public and private information can occur for two reasons: (i) the functions  $g$  and  $h$  differ so that the mappings from raw data to value estimates are not the same; and (ii) there is private information,  $z_i$ , that causes the firm to believe public estimates are inaccurate. If the firm believes that the function  $g$ , used to map known data to value estimates, seriously underestimates its leases' future productive potential, then the firm will have incentive to delay unit formation by withholding its leases in the expectation that subsequent production data will cause an upward revision in assigned shares. Further, the firm's engineers and geologists have access to company records, the accuracy of which cannot be verified by outsiders. If these records cause them to believe that future lease output (value) has been underestimated ( $\partial h / \partial z > 0$ ), then there will also be incentive to delay unit formation to await future production information that will be expected to increase  $\hat{V}_p^i$ .

These information problems aside, the firm may also decide to delay joining, if holding out will alter the allocation rule, (4), through concessions from the other parties since de-

lay causes aggregate losses. Theoretically, then, firms may hold out in an attempt to delay unit formation either due to differences in value estimates, where  $\hat{V}_f^i > \hat{V}_p^i$ , or because they want to alter the allocation rule. If the firm expects the incremental gains in assigned share from new information and strategic bargaining to offset the firm's share of losses in field value due to delay, the firm will not join. Formally, the firm will not join if

$$(8) \quad E_f(l_i) > (\beta_i - \alpha_i - s_i \lambda_i) / \eta,$$

where  $E_f(l_i)$  is the firm's expectation of the change in its unit share due to delay.

The special case where instantaneous profits are the same under open and unitized production,  $\beta_i = \alpha_i$ , yields intuitive insight into the problem. In this case, (8) implies

$$(9) \quad \frac{E_f(l_i)}{s_i} \equiv \frac{\partial s_u^i}{\partial t_u} \bigg/ s_i > \frac{-\lambda_i}{\eta} \\ \equiv - \int_{t_u}^T \frac{\partial \pi_u(t_u, t)}{\partial t_u} e^{-rt} dt \\ \bigg/ \int_{t_u}^T \pi_u(t_u, t) e^{-rt} dt.$$

In words, if the firm's expected percentage gain in share exceeds the percentage loss due to delayed unitization, the firm will not join.<sup>8</sup> There exists an expected share revision,  $l_i^*$ , which just creates an equality in (9) and is the dividing line between firms that want to join and those that want to delay. Because the right-hand side of (9) is strictly positive, the threshold value  $l_i^*$  must also be strictly positive. The probability that the firm will wish to delay, then, is the probability that  $E_f(l_i) > l_i^*$ . Because both estimates of value are unbiased,  $E_f(l_i)$  will have zero mean, and the probability that it exceeds  $l_i^*$  will

<sup>8</sup>Strategic bargaining aside, a necessary condition for (9) to hold is that the firm's private information leads to higher expected lease value than that based on public information.

depend critically upon the uncertainty of the public value estimates. As more lease information becomes known,  $\tilde{V}_p^i$  collapses around  $V_i$ , and the returns to waiting for more favorable information vanish. Hence, the probability that  $E_f(l_i) > l_i^*$  decreases monotonically with the reliability of public estimates of lease value.

Assume that  $E_f(l_i)$  is normally distributed with zero mean and variance  $\sigma$ , and define  $p(J)$  as the probability that lease  $i$  will join at time  $t$ ; then

$$(10) \quad p(J) = p\{E_f(l_i) \geq (\beta_i - \alpha_i - s_i \lambda_i) / \eta\} \\ = \Phi(\psi / \sigma),$$

where  $\Phi$  is the normal distribution function and  $\Psi \equiv (\beta_i - \alpha_i - s_i \lambda_i) / \eta$ . As the variance  $\sigma$  declines, the probability of joinder increases.

Figure 1 illustrates the impact of more precise public value estimates on the probability that a lease will join. The figure shows the density function for the firm's expectation of the change in share,  $E_f(l_i)$ , and the mean is equal to zero since both estimates of value are unbiased. As the variance of public estimates of lease value declines, the probability to the right of the threshold change in share,  $l_i^*$ , declines and the probability of joinder rises.<sup>9,10</sup>

This leads to an important implication that leases with more uncertainty regarding their value will be less likely to join units early in negotiations. We show below that these leases tend to be those with the longest productive lives and the greatest estimated values. Over time, greater information on lease values becomes available, uncertainty

FIGURE 1

declines, and public and private estimates of lease values collapse around the true value. Accordingly, the model implies that unitization contracts are more likely to be completed late in the primary productive life of the reservoir.

Another factor affecting the probability of delaying unit information is the location of the threshold  $l_i^*$  itself. A major influence on this threshold  $l_i^*$  is the size of the firm's holdings on the field (see (9)). As size increases, the firm will bear a larger share of the cost of delayed unitization. Hence, for a large firm to postpone joining, the expected share increase from delay must be larger, moving  $l_i^*$  to the right. This implies that very large firms on a field are more likely to join early.

Finally, a firm may delay joining for strategic bargaining reasons as we have noted above. In such cases the firm attempts to extract share concessions as a means of gaining ratification of unitization. In such circumstances the firm expects a positive  $E_f(l_i)$ , *ceteris paribus*.

There are other potentially important contracting problems. First, there will be some opportunity for the unit operator to take advantage of his position due to imperfect monitoring by other firms. Opportunism provides additional incentive for the operator to put his leases in the unit, but is a source of concern to other firms. A second problem we have referenced above is the case where a firm not only delays, but decides not to join the unit when it is finally formed. The firm's

<sup>9</sup>This generalizes beyond the normal density to any mean-preserving spread for any density so long as probability weight is being taken from  $[0, l_i^*]$  and placed to the right of  $l_i^*$ .

<sup>10</sup>Other factors affecting  $E_f(l_i)$  are the rate of change of the public information stock and strategic bargaining. The arguments in the text apply, *ceteris paribus*, for a given rate of change of these variables. To ease exposition the example chosen is where there is zero expected share change due to strategic bargaining.

decision rule under these circumstances is

$$(11) \quad \int_{t_u}^T \pi_n^i(t) e^{-rt} dt \\ > \int_{t_u}^T \pi_u(t) s_u^i(t_u) e^{-rt} dt.$$

In this case an all-or-nothing offer is being made by the unit to the firm to, effectively, play a positive sum game. The offer made must reflect what the firm can achieve independently or it will not play. Further, if the offer exceeds by any amount what the firm can achieve independently then, in general, it will accept.<sup>11</sup> We show below that certain firms systematically refuse these offers. Empirically, they are not offered greater shares to join after the unit is formed. In this case there must be disagreement regarding what the firm can independently achieve. Central to the firm's viability outside the unit is whether or not it has a large enough segment of the field to operate effectively as a separate entity. This is particularly important for secondary oil recovery. With secondary recovery, injection of natural gas or water increases pressure and would drive oil to adjacent areas unless the firm drilled injection wells along the perimeter of its leases. Hence there are substantial effective economies of scale for these secondary recovery projects. For small acreage, the added costs of injection wells would likely swamp any gains from separate secondary recovery. Therefore, a firm with large contiguous acreage will be better situated to remain independent of the unit if his private information suggests that his leases have higher values than public information suggests.

One task of the empirical analysis in Section III is to separate, where possible, the contracting problems due to information issues from those arising from a simple hold-

out strategy. The empirical observation that some firms choose to remain permanently out of a unit allows us to comment on hold-out strategies. Hold-out behavior is unlikely to be a major factor in the firm's decision not to join when a unit is formed, since firms who refuse to join are not later offered more favorable shares. Hence, holding out to increase one's share is not the motivation. Further, holding out to free ride on secondary recovery projects is also not empirically important. Firms that hold out often form their own subunits with neighboring firms, and cooperatively drill water injection wells along boundaries common with the unit to prevent oil migration between secondary recovery projects. This suggests that a firm's decision not to join is more complex than strategic bargaining to raise rental shares.

The theoretical discussion leads to a number of hypotheses to be tested in the empirical analysis in Section III:

1: As fields age, public and private information sources converge, making agreement on an allocation rule more likely.

2: Firms with large, scattered holdings on a field will be more willing to join and will also be more flexible in voting on allocation rules.

3: Similarly, firms with large blocks of contiguous acreage are more likely to withdraw and form separate units.

4: Leases where there is greater uncertainty of public estimates of lease value will be less likely to join a unit. It will be shown that high-output leases fit into this category.

5: Negotiation of allocation rules for assigning unitized rental shares will be constrained by disputes over estimates of structural characteristics.

6: Allocation rules must assign once-and-for-all shares, with no contingent updates.

7: Finally, the unit operator will be more likely to place a given lease in the unit, *ceteris paribus*.

The empirical analysis addresses the evidence concerning each of the (alternative) hypotheses. The discussion will generally be organized by hypothesis number.

<sup>11</sup> This decision is made recognizing that the firm will not be later offered a more favorable share. Such an offer would require a general renegotiation of shares, which is not possible. In this case, an all-or-nothing offer is made by the unit to the firm.

### III. Contracting on Seven Fields

The empirical bases for the study are unitization negotiations on seven Texas and New Mexico oil fields. Descriptive statistics for these fields and their unit negotiations are provided in Appendix A. Our examination of unitization contracting begins with a quantitative analysis of firms' decisions to place particular leases in the unit on the three oil fields for which we have sufficient data. The fields are North Cowden, Goldsmith/Landreth, and Prentice Northeast.<sup>12</sup> The theory presented above establishes the following partial derivatives for the probability that a given lease will be placed in a unit.<sup>13</sup>

$$(12) \quad J_{i,k} = f(A_i, C_{i,k}, Q_{i,k}, w_i, \varepsilon_{i,k})$$

$$f_1 > 0, f_2 < 0, f_3 < 0, f_4 > 0,$$

<sup>12</sup> The North Cowden field was discovered in 1930 and negotiations for the unit began in 1958 as the field neared depletion of primary reserves. An Engineering Committee was formed to collect parameter data from operators for assigning shares and to estimate gains from secondary recovery. In 1960 the committee estimated that recovery would increase by 100 million barrels, a gain of \$285 million in 1960 prices (Minutes, July 28, 1960, North Cowden Unit File, Company Records). Nevertheless, 19 of the 31 operators eventually withdrew part or all of their leased acreage, and a smaller unit was not formed until 1966, eight years after negotiations began. Contracting for the Goldsmith/Landreth unit began in 1961, but conflict over unit boundaries delayed work by the Engineering Committee until 1963. Four of the 10 operators bargaining for the unit withdrew leases in disagreement over allocation rules. Additionally, after a formula was finally agreed upon one firm withdrew eight more leases due to a dispute over secondary recovery plans. The final unit was not formed until October 1965. The Prentice field was discovered in 1951, and unit negotiations began in early 1954. Despite predictions that early unitization would substantially increase recovery, negotiations faltered, and were abandoned between 1956 and 1959. At that time the largest operator in the field attempted to reopen negotiations. By 1963 it was clear that field-wide unitization was not possible, and in late 1963 three units were formed, nearly ten years after negotiations were opened; the Northeast and Southwest units were operated by one firm and the central unit was operated by another.

<sup>13</sup> Strictly speaking, the hypothesis that  $f_3 < 0$  requires evidence (to be presented below) that increases in

where  $J_{i,k} = 1$  if lease  $k$  of firm  $i$  is placed in the unit, zero otherwise;  $A_i$  is firm  $i$ 's total acreage in the field;  $C_{i,k}$  is firm  $i$ 's acreage contiguous to lease  $k$ ;  $Q_{i,k}$  is the current output per acre on lease  $k$ ;  $w_i = 1$  if firm  $i$  is the unit operator, zero otherwise;  $\varepsilon_{i,k}$  is the error term; and where  $f_1 = \partial f / \partial A_i$ , and similarly for  $f_2$ ,  $f_3$ , and  $f_4$ . This equation can be used to test hypotheses 2, 3, 4, and 7. The assumption above that  $E_f(l_i)$  is normally distributed, and the binomial nature of the dependent variable requires a Probit estimation procedure for the joinder equation. Empirical results are presented in Table 2, part A. All coefficients are of the right sign and most are significant. Thus, the results generally provide strong support for the four hypotheses.

We have argued that firms with very productive leases will not place those leases into the unit. There is generally greater uncertainty about their value and disagreement over their share in the unit. The regression coefficients in Table 2, part A, are consistent with this notion. All of the output per acre coefficients are significant at the 10 percent level, and two are significant at the 1 percent level. Moreover, in Appendix B we show that there is greater uncertainty regarding predicted output levels for high output leases. We do this by regressing current output on all known structural characteristics and then examining the residuals. Those leases where uncertainty is highest will have the largest residual variance after adjusting for all factors known to affect output. We show that those leases with the highest output have larger unexplained (residual) variance. According to the theory, this should increase the probability that such leases will be withheld from the unit. The results of the estimations in Table 2 strongly support this hypothesis.

Qualitative evidence also indicates that the pattern of withholding very productive leases is consistent on all seven fields, despite ag-

lease output lead to greater uncertainty in value estimates.

TABLE 2<sup>a</sup>

	Intercept	Unit Operator	Lease Output per Acre	Firm Acres Contiguous to Lease	Total Firm Acres
A. Probit Estimations of Joinder Decisions <sup>b</sup>					
North Cowden	-.51 (.34)	11.7 (34.2)	-.0051 (.0032)	-.00096 (.00025)	.00050 (.00024)
$\chi^2 = 54.57$					
Goldsmith/Landreth	2.70 (1.01)	13.6 (13.5)	-.0118 (.0040)	-.0061 (.0014)	.00061 (.00063)
$\chi^2 = 39.49$

	9.67 (2.74)				
$F(1, 11) = 7.16$					.0066 (.0025)

<sup>a</sup>Standard errors are shown in parentheses.

<sup>b</sup>Dependent variable = 1 if lease is placed in unit; 0 otherwise.

<sup>c</sup>Dependent variable: the number of yes votes by firm in unit balloting (58 ballots).

gregate gains from a field-wide unit. On the Prentice field, a group of the most productive leases were located in the center of the field. After nine years of negotiations, efforts to form a single unit were abandoned because "a common formula could not be negotiated" (Minutes, Operators' Meeting, February, 1963, Prentice N.E. Unit File, Company Records). As a result three units were formed with separate secondary recovery projects. On the North Cowden field, firms with very productive leases voiced opposition to the proposed unit, with one firm asserting "none of the proposed parameters give justice to those leases because of their abnormal producing capabilities" (Letters, January 20, 1959; March 30, 1961, North Cowden Unit File, Company Records). Eight of the firms withdrawing acreage had ten of the most productive leases on the field. Output on those leases for the first six months of 1960 averaged 133 barrels per acre, while the average for all other leases was 79 barrels per acre (Engineering Report, December 1, 1960, North Cowden Unit File, Company Records). One unit proponent reported: "It is extremely difficult to arrive at a single factor which can be said to represent an equitable minimum, since the field is currently under active development and current production

relationships are changing with each month's data" (Letter, February 5, 1960, North Cowden Unit File, Company Records). Similarly, on Goldsmith/Landreth, three firms with unusually productive leases requested that acreage be deleted from the allocation rule. The three leases involved had average output per acre of 233 barrels for the period June 1962 to June 1963; only one other lease on the field had production of 200 barrels per acre, and average output for all other leases was 80 barrels, about one-third that of the withdrawn leases (1963 Engineers' Report, Table 4, Goldsmith/Landreth Unit File, Company Records). On the seven fields, owners of very productive acreage typically stressed that none of the formulas under consideration adequately protected their equity. Despite long negotiations (see Appendix A) and repeated formula adjustments (58 different votes on Empire Abo alone), consensus could not be reached on lease values and unit shares to attract the most productive leases into the unit. Thus, highly productive leases were systematically segregated from less productive leases and, where possible, separate subunits were formed.

When separate subunits were formed, independent secondary recovery projects were undertaken that were typically less effective

than field-wide projects. This indicates that firms could not agree on relative shares, since they were willing to bear higher costs. Moreover, there was no prospect of later renegotiation, and neither party was able to free ride on the other's secondary recovery efforts. Hence, parties disagreed about the relative values of leases, leading to a breakdown in negotiations. These observations suggest bargaining problems that are more complex than a simple hold-out problem.

Hypothesis 1 states that as field-wide primary depletion nears, consensus on unitization is more likely. The qualitative evidence from all seven fields supports this notion. Negotiations on North Cowden took eight years, in part, because some of the field was newly developed, while other parts were sharply declining. Much of the conflict centered on differences between new and older sections of the field. In withdrawing its lease from the unit, one firm notified the unit organizers that "the various parts of the field were simply so diverse that not one formula could satisfy everyone. We wish you every success in forming a unit in the center of the field where everything is more uniform" (Letter, September 4, 1963, North Cowden Unit File, Company Records). Similarly, agreement could not be achieved early in 1967 on Empire Abo when most leases could produce at regulated maximum production. Agreement could not be reached until 1971 as primary production declined.

The regression results in Table 2, part A, also support the notion that firms with large holdings on a given field will support unitization (hypothesis 2). This effect is measured by the total acreage variable, and the coefficients indicate that such firms were more willing to place their leases into the unit. These results are also backed by qualitative evidence. Firms with large holdings frequently made concessions to complete unit agreements. For example, on North Cowden, the largest firm estimated its 1959 output share at 37.5 percent of field production, but was willing to accept a lower minimum unit share of 36 percent (Letter, January 1, 1960, North Cowden Unit File, Company Records). On Goldsmith/Landreth, the concern of the largest firm regarding an increase in

unit costs due to the withdrawal of some leases is reflected as follows: "Although our reserves in the area from which all eleven tracks are eliminated are indicated to be greater..., our costs will undoubtedly be greater due to the requirement of additional injection wells..." (Letter, October 12, 1964, Goldsmith/Landreth Unit File, Company Records).

It was also predicted that firms with large acreage will support more allocation rules than will firms with small holdings. Data for 58 recorded ballots for 13 firms in Empire Abo negotiations allow for quantitative tests. In Table 2, part B, OLS regression results are reported for voting on Empire Abo:

$$(13) \quad Y_i = f(A_i; \eta_i); \quad f_1 > 0,$$

where  $Y_i$  = the number of yes votes by firm  $i$  in the balloting;  $A_i$  is firm  $i$ 's total acreage on the Empire Abo field; and  $\eta_i$  is the error term with zero mean, and it is assumed that  $A_i$  and  $\eta_i$  are independent. The test, then, examines the link between the total number of yes votes in repeated balloting and acreage. The coefficient for acreage is positive and highly significant, and these results are repeated elsewhere. On the Goldsmith San Andres field, the larger operators offered to give more than proportionately in share negotiations to speed the unit. In internal negotiating documents the firms recognized that they had 72.23 percent of current output, but they agreed to an aggregate share of 71.09 percent of remaining primary production under the unit and 67.80 percent of secondary recovery (Letter, October 27, 1961, Goldsmith San Andres Unit File, Company Records).

Firms with limited holdings, on the other hand, were more selective, supporting only specific allocation formulas that emphasized characteristics favoring their leases. For example, on the Slaughter Estate unit, one firm with 4 percent of acreage withdrew because the current output parameter used in the allocation formula supposedly undervalued its two leases. The firm had 2.81 percent of current production, but asserted that it had 3.53 percent of remaining oil reserves based on Engineering Committee estimates.

Two other firms with 4 and 2 percent of acreage, respectively, also threatened to withdraw for similar reasons (Letters, December 26, 1962, June 6, 1963, Slaughter Estate Unit File, Company Records). On Goldsmith San Andres none of the firms consistently voting no on allocation formulas had over 9 percent of field productive acreage. One small firm with only .3 percent of acreage voted no on all formulas offered. These small firms repeatedly called for adjustments in the weights placed on specific parameters to reflect their individual advantages: one firm with 5 percent of acreage and 1 percent of cumulative output called for less weight on the latter; another, with 4 percent of acreage and 2.8 percent of current output wanted current production removed or discounted. On the other hand, the three largest firms with 24, 16, and 15 percent of acreage, respectively, voted yes on all of the allocation rules submitted for consideration (Minutes, January 10, 12, 1962; February 7, 1962, Goldsmith San Andres Unit File, Company Records). In general, in contrast to the case where firms refused the final offer to join, evidence on voting behavior can reflect both information issues and hold-out strategies to increase rental shares.

The regression results in Table 2, part A, also support the notion that firms with large blocks of *contiguous* acreage will permanently withdraw and form their own units (see hypothesis 3, above). The coefficient for contiguous acreage is negative in all three fields and significant in two. On North Cowden, firms with large tracts of contiguous leases withdrew to form separate units. They included the second, fourth, and sixth largest firms by acreage on the field, and the withdrawn leases represented 97, 93, and 71 percent of the total acreage of these firms (Table 2, Engineers' Report, December 1, 1960, North Cowden Unit File, Company Records). On Western RKM, the second largest firm with 26 percent of acreage, all concentrated in the eastern part of the field, withdrew and formed its own secondary recovery unit.<sup>14</sup> The firm argued that the

parameters considered for share assignment "considerably underestimated" its lease values. The firm, along with other adjacent leases, formed its own secondary recovery unit (Letter, May 20, 1964, Western RKM Unit File, Company Records). On Prentice, the primary advocate of separate units had acreage of sufficient size concentrated in the center of the field for secondary recovery to be possible. In contrast, the unusually productive leases that were isolated in the northeast portion of the field finally joined the northeast unit; in part, because they were not large enough to be independently viable. As noted above, these decisions to remain outside a unit must be largely due to information issues and not a bargaining strategy.

The final coefficients in Table 2, part A, to be discussed are those for the unit operator variable. Hypothesis 7 is that the firm chosen to be unit operator would be more likely to place its leases into the unit. The regression results do not support this view; holding lease productivity, firm size, and contiguous acreage constant, the unit operator is not significantly more likely to place a given lease in the unit on all three fields.

There are two hypotheses not directly addressed by the regression estimates in Table 2. Hypothesis 5 is that the share parameters are limited because they must be based upon public information, and hypothesis 6 states that allocation rules must assign shares for all future periods. Qualitative evidence allows us to examine these hypotheses. The selection and interpretation of formula parameters were the central source of dispute on all seven fields. In general, agreement can only be reached for formulas using parameters that could be measured and interpreted without controversy. This sharply limits contractual flexibility because of the small number of objectively measurable variables and the highly tenuous nature of even modest extrapolations as discussed in Section I. Even simple static structural char-

<sup>14</sup>In March 1962, a 26,400 acre RKM unit was planned on the Slaughter field, but was soon dropped in

favor of a smaller 9,911 acre unit. Negotiations continued through 1966. By that time 50 percent of the leases, covering 4,993 acres, had been withdrawn. Most were on the eastern side of the proposed unit, leaving only 4,918 acres in the final agreement.

acteristics, such as the thickness of the reservoir rock and pore space available for holding hydrocarbons, were sources of significant dispute. For example, early in unit negotiations the Engineering Committee on North Cowden reported that data were too sketchy to calculate "a fair and equitable" gross or net pay under each lease (the gross thickness of the reservoir or the thickness net of any nonproductive zones). The Committee only had well cores for 28 of the 733 wells on the field, and it stressed the "meager data and poor quality of available records" (Memo, April 7, 1959, North Cowden Unit File, Company Records). As a result, during the eight years of negotiations for the North Cowden unit, nearly all of the numerous parameter formulas considered were simple convex combinations of current and cumulative output, which were available and reliable for all leases. Attempts to incorporate more sophisticated parameters met with objection due to their subjective nature given the lack of available data: "a disadvantage [of gross pay] is that we are basing a parameter of unitization on the skill or lack of skill in the persons observing the samples. Therefore, there is considerable question as to the consistency of the picks [estimates] between wells, and it would likely be difficult to reach agreement between operators on such data..." (Letter, June 16, 1959, North Cowden Unit File, Company Records). Moreover, remaining reserves could not be estimated in ways acceptable to all operators. The unit operator had access to reservoir data and could have estimated the parameter, but its estimates would have been controversial. Instead, it chose to release the data to the Engineering Committee for parameter calculation. Even so, one small firm hired an outside consultant to calculate its net reserves, and got values double those calculated by the Engineering Committee (Letters, January 9, 1962; March 8, 1963, North Cowden Unit File, Company Records).

Disputes over the measurement of static reservoir characteristics occurred as well on other fields. On Prentice Northeast, the owner of the most productive acreage believed that its reservoir pore space had been badly underestimated. Reconciliation took several

months and finally resulted in an *ad hoc* upward adjustment of 70 percent, and led to a large increase in the firm's unit share. A major information problem was that observations were limited to wells, and the extrapolation method used between wells dramatically altered parameter calculations. For example, a linear versus a log-linear extrapolation of reservoir depth between wells created significant differences in estimated reservoir volume under particular leases. When the reservoir was highly variable or when observations for a large percentage of wells were unavailable, as on Cowden, the issues were extremely difficult to resolve. On Prentice Northeast, the final formula accepted included one observable and measurable variable, current production. Estimates of primary recovery for the leases were made using a variety of techniques, but "Relatively poor agreement between various methods were obtained in many instances. Primary reason for inconsistencies [was] due to a severe lack of control in much of basic data together with inherent uncertainties involved in these type calculations." Core analyses done by differing consulting firms gave dramatically different results (Engineering Committee Minutes; Letter, June 29, 1963, Prentice N.E. Unit File, Company Records). These data problems persisted in 1963, even though Prentice Northeast was fully developed and two-thirds depleted. The inability to precisely estimate reserves at the field level is not a serious obstacle to contracting. Disputes about reserves and future productivity, however, are repeated at the lease level, where they break down share negotiations.

Finally, as predicted in hypothesis 6, the accepted formulas for each unit assigned *permanent* shares. Contingent updates are not feasible because unitization fundamentally changes the pattern of reservoir production. Some wells are plugged, others are converted to injection, and new wells are drilled, completely altering the pattern of migration. Hence, after unitization it is impossible to infer the oil in place or the oil that could have been produced from a given lease. In no case have we encountered a unit where contingent updates were allowed. Evidence of the once-and-for-all nature of the con-

tracts is that the allocation formulas adopted were often multiphase, but established a set pattern of share adjustment, based on data known at the time of agreement. Because unit shares were fixed, those firms most concerned about biases in their fair share calculation due to incomplete information would be reluctant to join, based on existing evidence. We have identified those firms as owners of very productive leases, and their tendency to withdraw from unit contracting has been documented above. If contingent updates were possible, negotiations could allow for temporary shares to entice early agreement with corresponding aggregate gains, and share adjustments could be negotiated as more information became available.

Before turning to the conclusions, it is worth briefly reviewing the hold-out issue. Previous studies of unitization (see, for example, Stephen McDonald) have casually concluded that the primary obstacle to unitization is simple strategic bargaining to increase unit shares, rather than real differences in opinion regarding relative lease values. Clearly an element of both may be present in a given situation, and in many contexts it is difficult to distinguish between "honest" differences and pretended differences to gain an advantage. In the present context, however, there is evidence presented above that shows information problems play a critical role in contractual failure for unitization. The first of these is that the firms' joinder decisions involved a decision to permanently withdraw from the unit. The purpose of a strategic hold out is to gain a more favorable offer later; yet, for all of the decisions represented by the regressions in Table 2, part A, the decisions were once and for all. For these cases, then, strategic bargaining by either party was not the point. Second, a pure strategic hold-out hypothesis also would predict that high- and low-output leases are equally likely to delay the unit or refuse to join. The systematic differences in behavior evident between these groups is inconsistent with a simple hold-out hypothesis, and yet follows naturally from the imperfect information argument. Furthermore, breakdown in unit negotiations often led to the formation of multiple subunits on fields such

as Prentice. Here, the problems of reconciling differences in the value of highly heterogeneous leases were repeatedly cited. The operators, in explaining why they would not (and later *did not*) join a unit, claimed that the heterogeneities could not be reconciled. These same operators, then, contemporaneously formed partial units with other operators having similar, neighboring leases. A hold-out strategy does not explain why these operators would withdraw from one unit and form another.

Third, we have a very interesting set of observations from unitization on federal lands in Wyoming. The federal government actively encourages unitization through policies that facilitate agreement (see our earlier paper).<sup>15</sup> On federal lands, agreements can be reached prior to the drilling of any wells—a period when *private* information about lease characteristics such as well performance will be limited and known lease heterogeneities are minimal. Units formed at this time take less than six months to negotiate, and the percentage of production that is unitized is very high. Further, there is little dispute chronicled in the negotiation records. If, however, the unit is formed later after production has begun, and lease heterogeneities and asymmetric information have emerged, then negotiations take an average of seven years and are frequently acrimonious. Hence, the federal policies work well before asymmetric information and heterogeneities have emerged, but have little impact if agreement is not reached during that period. A simple hold-out strategy cannot easily explain why the commencement of production fundamentally changes the character, speed, and success of unit contracting.

None of this is to suggest that hold outs are an unimportant problem in unitization. Instead, the analysis of this paper shows that information problems play a critical role,

<sup>15</sup> General policy responses to the unitization problem are beyond the scope of this paper. Our forthcoming paper presents analyses of the impact of different unitization policies in Oklahoma, Texas, and federal lands on the speed and extent of unitization. We also offer reasons for sharp policy differences across these political jurisdictions.

and explain much observed behavior that is otherwise difficult to unravel.

#### IV. Concluding Remarks

Private contracting is a common solution to many problems in production and exchange. When there exists a core of exchange, contracts permit parties to move into the core, and general welfare is improved. Recent analyses of contracting by Goldberg, Williamson, and others, however, have introduced a point of caution—information asymmetries, opportunism, and small numbers bargaining problems can break down the contracting process in cases where there is a need to sequentially update contract terms to reflect changes in the economic environment. These findings limit the range of problems where contracting can be an effective solution in resource allocation.

Our results have more serious ramifications for the general applicability of contracts. The study has analyzed an important empirical setting where private contracting has not been successful. Despite large net gains from unitization, *ex ante* imperfect information and information asymmetries among the negotiating parties regarding lease values prevents consensus on unit shares. These problems exacerbate any hold-out strategies that would otherwise impede agreement. As a result, contracts are often either not completed or are very incomplete with only fragmented units. Even simple once-and-for-all contracts that need little subsequent adjustment systematically break down. While one can think of a variety of hypothetical mechanisms for eliciting the information needed for agreement in an incentive compatible form, they are not observed.

We believe that the informational imperfections and asymmetries that lead to contractual failure in unitization are repeated in many contexts. Examples include labor markets and the problems of evaluating heterogeneous workers and contracting for pollution control. Our analysis suggests that an assumption that private contracting will solve inefficiencies in these areas is unwarranted. Accordingly, close attention by economists

to contracting details in a variety of settings is required for a better understanding of economic processes and events.

#### APPENDIX

##### A. Contracting Summary

Table A1 outlines the general contracting conditions for the seven fields examined in the paper. The table reveals the long bargaining time before agreements were reached. Moreover, the table shows that in every case but Empire Abo a subunit was formed, rather than a complete field-wide unit. Empire Abo is on federal land in New Mexico where compulsory unitization rules apply to force nonjoinders into the unit.<sup>16</sup>

##### B. Lease Output and Uncertainty of Lease Value

Here we demonstrate that highly productive leases have more uncertainty regarding their value than do less productive leases. Uncertainty is measured with respect to the publicly available data regarding lease characteristics. Greater uncertainty in public estimates of lease value implies, *ceteris paribus*, a greater probability of relatively large changes in expected share ( $E_f(l_i)$ ). In other words, the probability to the right of  $l_i^*$  in Figure 1 is larger. This makes it less likely that the lease will be placed in the unit. We test this proposition regarding high output leases in Section III.

In order to establish greater uncertainty in public estimates of lease value, we examine data concerning current output and all known basic reservoir characteristics. The argument is that inability to accurately predict current output using all known lease characteristics is equivalent to being unable to predict future output and, hence, current value. What we wish to show is that there is greater residual uncertainty regarding current output for highly productive leases than for less productive leases.

<sup>16</sup> Compulsory unitization rules do not exist in Texas; see our forthcoming paper.

(B)	367.1 (.40)				824 (.04)	1.55 (2.63)

Note: Equation (A): Dependent variable = Output per acre; Equation (B): Dependent variable = Squared residual from Equation (A).

<sup>a</sup>t-values are shown in parentheses. Independent variables are different across fields solely because of differing data limitations in unit negotiation records. In all cases, the available independent variables used were those not calculated exclusively from current output.

To show this we perform a simple heteroscedasticity test. We first regress current output on *all* known lease characteristics, such as past output, number of wells, and reservoir thickness. We then examine the residuals of this regression. The null hypothesis is that the residuals are homoscedastic, while the alternative is that leases with higher output will have larger residuals than those with lower output. To test for this we estimate a second regression with the squared residuals

from the first regression on the left-hand side and the same set of variables on the right. The null hypothesis is rejected if all variables that are statistically significantly different from zero in both regressions also have the same sign in both regressions.

The regression results are reported in Table A2. For each field the null hypothesis of homoscedastic residuals is rejected at the 10 percent confidence level and for two of the three fields the null hypothesis is rejected at

the 5 percent confidence level.<sup>17</sup> Hence, there is greater residual uncertainty regarding prediction of current output from known lease characteristics for high-output leases than for low-output leases. Thus there are wider confidence bands on public estimates of output for these very productive leases. This increases the probability, *ceteris paribus*, that firms will have private information that causes them to believe that a substantial revision in share will be forthcoming, if the unit is delayed. In a Bayesian sense the strength of the prior, based upon public information, is less. Similarly, it increases the probability that they will not join a given unit because they believe their property is sufficiently undervalued that they can do better on their own. This proposition is tested in Section III.

<sup>17</sup> Under the null hypothesis, these tests are unbiased.

# Anticipated Devaluations, Currency Flight, and Direct Trade Controls in a Monetary Economy

By ROBERT C. FEENSTRA\*

While a devaluation is the usual recommendation for a country facing a balance of payments deficit, this advice is often resisted by country governments. Instead, direct trade controls such as tariffs, quotas, and subsidies are frequently used. In this paper I propose an economic explanation for the reluctance to devalue and the use of trade controls, namely, the "currency flight" that can be expected to occur if the devaluation is anticipated. In an effort to avoid or offset the effects of this currency flight, countries may use direct controls. I shall analyze the properties of using import tariffs and export subsidies, with or without an anticipated devaluation, to affect the balance of payments and obtain the social optimum.<sup>1</sup>

Specifically, I shall identify three reasons for using direct trade controls when faced with a balance of payments deficit:

- 1) An equal import tariff and export subsidy will lower consumption and improve the balance of payments through a real balance effect, but will not cause speculative activity so long as goods are nondurable;

- 2) Prior to an anticipated devaluation we expect a depreciation of the black market exchange rate, and an import tariff is needed to offset the incentive to hoard foreign exchange and consume foreign goods;

- 3) When a social foreign exchange constraint is binding, a planner will shift consumption away from the import good, and a

long-run import tariff is needed to ensure that consumers follow this socially optimal plan.

The equivalence between a uniform tariff-cum-subsidy policy and a devaluation is well known (see Richard Caves and Ronald Jones, 1981, p. 355, and Gerald Meier, 1980, p. 170). It is also clear that with nondurable goods the tariff-cum-subsidy will not cause speculative activity, in contrast to the anticipated devaluation.<sup>2</sup> This is my first reason for using tariffs and subsidies. Second, in the absence of exchange controls, the currency flight caused by an anticipated devaluation will drain the central bank of reserves and create a black market in foreign exchange, and I shall solve for a depreciation of the black market exchange rate. The depreciation causes the consumer to substitute foreign for domestic money in asset holdings, and consume relatively more of the foreign good. This distorting effect on consumption can be offset by using an import tariff.

The third reason I identify for using trade controls is more specific to the model structure. In Section I, I describe a small country, intertemporal trade model where money is introduced by a continuous time version of "cash-in-advance" constraints, as originally proposed by Robert Clower (1967). It is assumed that the consumer uses domestic (foreign) money to purchase domestic (foreign) goods, and thus faces two cash-in-advance or transactions constraints. By endowing the consumer with large holdings of

\*Department of Economics, Columbia University, New York, NY 10027. I have benefited from the comments of seminar participants at Carleton, Columbia, Minnesota, Princeton, and Rochester universities. Special thanks go to Ronald Findlay for suggestions that have significantly improved this paper.

<sup>1</sup>Using the equivalence shown by Jagdish Bhagwati (1969), the import tariffs could be replaced by import quotas. In this sense, I do not maintain any distinction between price and quantity controls.

<sup>2</sup>This contrast between a tariff-cum-subsidy policy and anticipated devaluation can be further understood by recognizing, as in Bhagwati (1968, p. 63), that for full equivalence between the two policies the tariffs and subsidies should apply to the current and capital account. Since the direct trade controls I analyze do not apply to the capital account, and goods are nondurable, these controls do not cause speculative activity.

domestic money, the desired consumption level is high and a balance of payments deficit occurs. Various policies to obtain balance of payments equilibrium, such as equal tariffs and subsidies or a devaluation, are examined in Section II.

In Section III, I argue that the social planner faces *only* a transactions constraint in foreign exchange, since any amount of domestic money could in principle be created to avoid the domestic constraint. It follows that the policies analyzed earlier to secure balance of payments equilibrium are not sufficient to obtain the social optimum. In Section IV, I examine methods to obtain balance of payment equilibrium and decentralize the optimum. In particular, it is found that an import tariff greater than the export subsidy is needed when the social foreign exchange constraint is binding, giving the third reason for the use of trade controls. In the concluding section, I discuss the relation of the analysis to existing literature. The formal proofs of lemmas and propositions have been omitted for brevity, but are contained in a working paper, available on request.

### I. The Model

On the production side, let us assume a Ricardian economy, where every unit of labor produces one unit of the export good. The foreign exchange price of the exportable, importable, and domestic money are all normalized at unity under *laissez-faire*. Both goods are nondurable. The representative consumer faces the transactions constraints

$$(1) \quad M \geq \alpha C_1, \quad M^* \geq \alpha C_2,$$

where  $M$  and  $M^*$  are holdings of the domestic and foreign money, respectively;  $C_1$  and  $C_2$  are consumption of the exportable and importable; and  $\alpha$  is a parameter which can be interpreted as the length of time money must be held to finance consumption.<sup>3</sup> Discrete time versions of these

cash-in-advance constraints applied to international trade models have been used by Elhanan Helpman (1981a, b), Helpman and Assaf Razin (1979), Robert Lucas (1982), Torsten Persson (1984), Alan Stockman (1980), and Lars Svensson (1985); recent surveys of autarky and trade models with such constraints are provided by Meir Kohn (1984), and Maurice Obstfeld and Stockman (1984, Sec. 5).

I shall assume that consumers are permitted to instantaneously exchange any amount of domestic money for foreign money with the central bank, at the price of unity. Thus, I am assuming no exchange controls. This framework clearly exaggerates the availability of foreign exchange in many developing countries. It has the advantage, however, of leading to a particularly simple form of currency flight: in response to an anticipated devaluation, consumers will exchange domestic for foreign money with the central bank until  $M = \alpha C_1$ , and thereby drain some of the government's foreign exchange reserves. In the following section I shall consider the implications of the consumer's demand for foreign exchange exceeding available reserves.

I shall further assume that there are no domestic or foreign bonds, so the consumer's assets are given by  $A \equiv M + M^*$  (recalling that the exchange rate is unity). The absence of assets other than money is mainly used to simplify the model, but also exaggerates the limited extent of capital markets in many developing countries (see Ronald McKinnon, 1973). Assets  $A$  are a state variable of the system, and changes over time according to  $\dot{A} = L - C_1 - C_2$ . The variable  $L$  is the fixed quantity of labor supplied and equals income with the wage equal to the exportable price of unity, while  $C_1 + C_2$  is the value of expenditure.

Denoting the instantaneous utility function by  $U(C_1, C_2)$ , the representative con-

<sup>3</sup>Formally, I could write the transactions constraint for domestic money as  $M(t) \geq F(\alpha) \equiv \int_t^{t+\alpha} C_1(s) ds$ ,

and similarly for foreign money. A Taylor-series expansion gives  $F(\alpha) = \alpha C_1(t) + \frac{1}{2} \alpha^2 \dot{C}_1(t) + \dots$ , and so (1) can be interpreted as a first-order approximation.

sumer solves the problem

$$(2) \quad \max \int_0^{\infty} e^{-\rho t} U(C_1, C_2) dt$$

subject to  $M \geq \alpha C_1$ ,  $M^* \geq \alpha C_2$ ,

$$\dot{A} = L - C_1 - C_2, \quad A(0) = A_0,$$

where the initial value of assets  $A_0 = M_0 + M_0^*$  is assumed greater than  $\alpha L$  so the value of consumption can exceed labor income, and  $\rho$  is the discount rate.

Before formally solving this problem, an intuitive treatment is helpful. Suppose the consumer has made an optimal savings decision (i.e., chosen  $\dot{A}$ ), and then faces the budget constraint  $C_1 + C_2 = L - \dot{A}$  shown as  $BB$  in Figure 1. With a constant exchange rate of unity, and instantaneous exchanges between domestic and foreign money permitted at the central bank, the constraints (1) can be combined into

$$(1') \quad A \geq \alpha(C_1 + C_2).$$

If at a point in time the consumer has large asset balances, then the transactions constraint (1') may be illustrated as  $RR$  in Figure 1, which is not binding given the budget constraint  $BB$ . In this case, consumption would occur at  $P$ , where the marginal rate of substitution along the indifference curve  $U$  equals the ratio of international prices.

Alternatively, with small money balances the transactions constraint may be illustrated by  $R'R'$  in Figure 1, lying inside the budget constraint  $BB$ . In this case consumption would occur at  $P'$ , and the consumer would experience "forced savings" due to an inability to satisfy the transactions constraint at the desired consumption level. It is important to notice that at  $P'$ , the marginal rate of substitution still equals the ratio of international prices, since the budget and transactions constraints are parallel.<sup>4</sup>

<sup>4</sup>The budget and transactions constraints are parallel since I have assumed the same value of  $\alpha$  in the domestic and foreign transactions constraints (1). If different values of  $\alpha$  were used in the two constraints in (1), then this would imply a further reason for using direct trade controls to support the social optimum.

FIGURE 1

Turning to a formal solution of problem (2), when the consumer is *liquid* (i.e.,  $M > \alpha C_1$  or  $M^* > \alpha C_2$ ), the optimality conditions are

$$(3) \quad U_1 = U_2 = \theta, \quad \dot{\theta} = \rho\theta,$$

where  $U_i = \partial U / \partial C_i$  for  $i=1,2$ , and  $\theta$  is interpreted as the shadow value of wealth.<sup>5</sup>

When the consumer is *illiquid* (i.e.,  $M = \alpha C_1$  and  $M^* = \alpha C_2$ ), then the optimality conditions can be written as

$$(4) \quad U_1 = U_2 = \theta + \alpha\phi, \quad \dot{\theta} = \rho\theta - \phi,$$

where  $\phi \geq 0$  is a Lagrange multiplier that is positive when the transactions constraints (1) are binding. Note that the optimality conditions still ensure that  $U_1/U_2=1$ , so the marginal rate of substitution equals the ratio of international prices. Differentiating the

<sup>5</sup>These conditions are obtained from the current value Hamiltonian  $H = U(C_1, C_2) + \lambda_1(M - \alpha C_1) + \lambda_2(M^* - \alpha C_2) + \phi(A - M - M^*) + \theta(L - C_1 - C_2)$ , with the optimality conditions  $\partial H / \partial C_i = \partial H / \partial M = \partial H / \partial M^* = 0$  and  $\dot{\theta} = \rho\theta - \partial H / \partial A$ ,  $i=1,2$  ( $\theta$  can be interpreted as the shadow value of wealth). When the consumer is liquid then  $\lambda_1 = \lambda_2 = \phi = 0$ .

FIGURE 2

binding transactions constraint and using  $A = L - C_1 - C_2$ , we obtain

$$(5) \quad (\dot{C}_1 + \dot{C}_2)/(C_1 + C_2) = -(1/\alpha)[1 - L/(C_1 + C_2)].$$

For convenience let us assume that the instantaneous utility function is homogeneous of degree  $(1 - \sigma)$ ,  $0 < \sigma < 1$ . It follows from (3) that when the consumer is liquid,  $C_1$  and  $C_2$  both fall at the exponential rate  $\rho/\sigma$ . Also, note that in the long run the value of consumption  $(C_1 + C_2)$  will converge to wage earnings  $L$ , since in the absence of capital markets the savings obtained by foregoing current consumption and choosing  $(C_1 + C_2) < L$  could only generate extra consumption in the future, which would be suboptimal. The remaining question, then, is to determine when the transactions constraints are binding so the consumer is illiquid.

**LEMMA 1:** *The consumer is liquid (illiquid) according as  $C_1 + C_2 > (<) \beta_1 L$ , where  $\beta_1 \equiv 1/(1 - \alpha\rho/\sigma) > 1$ .*

The proof of this lemma rests upon setting (5) equal to  $-\rho/\sigma$ , which yields the point at which the consumer shifts from being liquid to illiquid;  $\alpha\rho/\sigma < 1$  is assumed.

The economy's consumption path is shown by  $ABC$  in Figure 2. Along  $AB$  the consumption of both goods falls at the exponential rate  $\rho/\sigma$ . The range over which the consumer is illiquid is shown by  $BC$ , where the value of consumption falls more slowly than  $\rho/\sigma$ , as indicated by (5). At every point of time, consumption exceeds labor income, so the economy has a balance of trade deficit. This deficit is financed by a reduction in the consumer's cash balances, which leads to a demand for central bank reserves whenever the consumer switches from domestic to foreign money to purchase the import. In the following section I discuss methods to obtain balance of payments equilibrium in the economy.

## II. Balance of Payments Equilibrium

With consumption exceeding labor income along the path  $ABC$  in Figure 2, the economy has a balance of trade deficit. The accumulated long-run deficit is given by the reduction in asset holdings (i.e.,  $A_0 - \alpha L$ , where  $\alpha L$  are the long-run asset holdings of the consumer as  $(C_1 + C_2)$  approaches  $L$ ). The total demand for central bank foreign exchange is then given by the integrated balance of trade deficit less the reduction in the consumer's foreign asset holdings, that is,

$$(6) \quad (A_0 - \alpha L) - (M_0^* - \alpha\gamma_2 L) = M_0 - \alpha\gamma_1 L,$$

where  $\gamma_i$  is the marginal and average propensity to consume good  $i$ , so  $\alpha\gamma_i L$  is the consumer's long-run holdings of domestic ( $i = 1$ ) and foreign ( $i = 2$ ) money.

If we now assume that initial central bank reserves of foreign exchange, denoted by  $R_0^*$ , are less than the accumulated private demand for foreign exchange given in (6), then the economy faces an unsustainable balance of trade deficit. Let us suppose that the central bank reserves include all available foreign borrowing (assumed to occur at a zero interest rate for simplicity). Several methods can then be considered to accommodate the trade deficit.

### A. Monetary Policy and Direct Trade Controls

First, a reduction in consumer holdings of domestic money will reduce the demand for foreign exchange. From (6), the level of initial money holdings needed to ensure that foreign exchange demand can be financed by available reserves is simply  $M'_0 = R^*_0 + \alpha\gamma_1 L$ . Second, an unanticipated devaluation would lower the foreign exchange value of domestic money holdings, and therefore have the same impact as directly reducing domestic balances.

Third, an equivalent way to restore balance of payments equilibrium is to impose an equal import tariff and export subsidy, thereby raising domestic prices. The higher domestic prices will have a real balance effect on consumption expenditure and thus reduce the balance of trade deficit. This uniform tariff-cum-subsidy policy ensures that the consumer's marginal rate of substitution equals the ratio of international prices: in the following section I shall examine the social optimality of such a policy.

The first two methods discussed above—reducing domestic money holdings and the unanticipated devaluation—may not be available to government authorities in a less developed country. In the absence of substantial capital markets, the central bank cannot rely on an open market operation to reduce money holdings, and in practice may attempt a recoinage of the domestic currency. This policy is essentially equivalent to the unanticipated devaluation that could not be used repeatedly. Accordingly, I shall next examine a devaluation which is anticipated.

### B. Anticipated Devaluation

Let us consider a devaluation which is *anticipated* from  $t = 0$ . Suppose that at time  $T'$  the central bank will devalue the domestic currency, raising the official price of foreign exchange from unity to  $x' > 1$ . As in Paul Krugman (1979) and Obstfeld (1984), I wish to solve for the perfect foresight path of the exchange rate between time 0 and  $T'$ . I shall impose exchange controls when the central bank is drained of foreign exchange

reserves, so that no more purchases can be made.<sup>6</sup> In that case a black market for foreign exchange is created with a floating exchange rate. Arbitrage and perfect foresight will ensure that the floating exchange rate is continuous after time 0, though it can jump initially, and equals the official rate  $x'$  at time  $T'$ .

The path of the floating exchange rate is solved from the conditions of portfolio equilibrium for the consumer. When the consumer is liquid, the optimality conditions are given by<sup>7</sup>

$$(7) \quad U_1 = \theta(1 + \alpha\dot{x}/x),$$

$$U_2 = \theta, \quad \dot{\theta} = \rho\theta,$$

which reduce to (3) when  $\dot{x} = 0$ . So long as the exchange rate is depreciating along this path, the consumer will not hold any domestic money balances in excess of those needed for consumption, and so  $M/x = \alpha C_1$ . If the central bank's reserves have been drained, then the consumer's holdings of domestic money must be  $M_0 - R^*_0$ , that is, initial holdings less the sale of domestic money to the central bank at the exchange rate of unity. Substituting these relationships into (7) we obtain

$$(8) \quad U_1[(M_0 - R^*_0)/\alpha x, C_2] = \theta(1 + \alpha\dot{x}/x)$$

$$U_2[(M_0 - R^*_0)/\alpha x, C_2] = \theta, \quad \dot{\theta} = \rho\theta.$$

<sup>6</sup>In Section IV, I shall permit the central bank to retain some amount of reserves before exchange controls are imposed, and gradually deplete these reserves in supporting the social optimum (see fn. 11). For simplicity, I do not examine this case now. Obstfeld also considers the case where exchange controls are imposed before reserves are drained, and Jorge de Macedo (1982) examines exchange rate behavior under currency inconvertibility.

<sup>7</sup>Assets are now given by  $A = M/x + M^*$  and so  $\dot{A} = \dot{M}/x + \dot{M}^* - (M/x)(\dot{x}/x) = L - C_1 - C_2 - (M/x)(\dot{x}/x)$ . It follows that the current value Hamiltonian is given by  $F = U(C_1, C_2) + \lambda_1(M/x - \alpha C_1) + \lambda_2(M^* - \alpha C_2) + \phi(A - M/x - M^*) + \theta\dot{A}$  with the optimality conditions  $\partial F/\partial C_i = \partial H/\partial M = \partial H/\partial M^* = 0$  and  $\dot{\theta} = \rho\theta - \partial H/\partial A$ ,  $i = 1, 2$ . When the consumer is liquid, then  $\lambda_2 = \phi = 0$ .

FIGURE 3

By inspection, the path of the floating exchange rate is solved from (8) as

$$(9) \quad x = x_0 e^{(\rho/\sigma)t}$$

To see this, with the exchange rate depreciating at the rate  $\rho/\sigma$ , then  $C_2$  also falls at this exponential rate in (8) and the marginal utilities rise at the rate  $\rho$ , as required. The initial value of the exchange rate is simply obtained by setting  $x(T') = x'$  and then inverting (9) to obtain

$$(10) \quad x_0 = x' e^{-(\rho/\sigma)T'}$$

If the initial value of the exchange rate  $x_0$  from (10) exceeds unity, indicating a discrete depreciation, then the central bank reserves are completely drained at time 0 and a black market for foreign exchange is created. In this case the path of the floating exchange rate is shown by  $X_0Y_0$  in Figure 3. Along this path the exchange rate continuously depreciates at the exponential rate  $\rho/\sigma$ , and equals the official rate at the time  $T'$ .<sup>8</sup>

<sup>8</sup>It appears that we cannot rule out a second equilibrium path, in which the exchange rate jumps to  $x'$

A slightly different path is obtained if knowledge of the devaluation *does not* drain the central bank's reserves at  $t = 0$ . Thus, in Figure 3 suppose the official devaluation will occur at time  $T''$ , where the value of  $x_0$  obtained from (12) indicates a discrete *appreciation* initially. However, it is impossible for the black market rate to appreciate when the central bank is prepared to sell domestic currency at the price of unity. It follows that the exchange rate is constant at unity until the time  $\bar{T}$ , when central bank reserves are exhausted.

Up to  $\bar{T}$  the consumption of both goods falls at the exponential rate  $\rho/\sigma$  (assuming the consumer is liquid, as described in Lemma 1). Falling demand for the exportable implies that domestic currency requirements to satisfy the transactions constraint are also falling, and so this domestic money is used to purchase foreign exchange. At time  $\bar{T}$  the central bank reserves are drained, and currency trading in the black market begins to operate. After this time along the path  $X_1Y_1$ , the floating exchange rate depreciates at the rate  $\rho/\sigma$ , and equals the official rate at  $T''$ .

After the official devaluation has occurred (at  $T'$  or  $T''$ ), the central bank has a zero stock of reserves, but the official market still finances the flow demand for foreign exchange. That is, the official rate  $x'$  is chosen so that the supply of foreign exchange from exports equals the value of imports minus the reduction in the consumer's foreign exchange holdings. This choice of  $x'$  achieves balance of payments equilibrium, as will be illustrated in Section IV. In the long run, the consumer's foreign exchange holdings approach  $\alpha\gamma_2L$ , and the flow supply of foreign exchange from exports just equals the value of imports.

immediately. The multiple equilibria occur since, unlike the models of Krugman and Obstfeld, the allocation of assets beyond those needed for transactions is indeterminate when the expected devaluation is zero. Since I wish to illustrate the possible inefficiency which arises from currency flight, I shall focus on the equilibrium path with a depreciating black market rate.

An important question is whether the floating exchange rate path implied by the currency fight and resulting black market imposes any welfare cost on the economy. Intuitively, one expects that the depreciating exchange rate will lead the consumer to forgo some consumption of the exportable and therefore reduce holdings of domestic currency required for transactions. With  $\alpha$  units of domestic money needed per unit of the exportable and the exchange rate depreciating at the rate  $\rho/\sigma$ , the relevant price of the exportable becomes  $(1 + \alpha\rho/\sigma)$ . As is verified from (7) and (9), the consumer's marginal rate of substitution equals  $(1 + \alpha\rho/\sigma)$  along the floating exchange rate path. In Figure 1, consumption occurs at a point such as  $Q$ , with less consumption of the exportable and greater consumption of the importable than at a point of tangency between the indifference curve and budget constraint.

In contrast the point  $P$ , where the marginal rate of substitution equals the ratio of international prices, is obtained under the uniform tariff-cum-subsidy policy discussed above. It is clear that to evaluate the merits of direct trade controls over the anticipated devaluation we must first solve for the social optimum. This is done in the next section, where I consider the optimum obtained by a central planner with full control over all variables. Section IV then examines various means to decentralize the social optimum.

### III. Social Optimum

A social planner faces the same problem as the representative consumer, but has the ability to print any amount of domestic money. It follows that the transactions constraint  $M \geq \alpha C_1$  will never be binding, and can be ignored. In addition, the social planner has access to all foreign exchange in the economy (i.e., that of the consumer ( $M^*$ ) and central bank ( $R^*$ )). Denoting these foreign exchange holdings by  $F^* \equiv M^* + R^*$ , the social planner solves

$$(11) \quad \max \int_0^\infty e^{-\rho t} U(C_1, C_2) dt$$

subject to  $F^* \geq \alpha C_2$ ,  $\dot{F}^* = L - C_1 - C_2$ ,

$$F^*(0) = M_0^* + R_0^*,$$

FIGURE 4

where  $(L - C_1)$  are exports of good 1,  $C_2$  are imports of good 2, and so  $(L - C_1 - C_2)$  is the balance of trade deficit and flow reduction in foreign exchange.

It should be noted that while the constraint  $M \geq \alpha C_1$  in (11) is ignored, when we decentralize the solution we shall never consider policies in which a large (or any) amount of domestic money is printed. Instead, a zero shadow value on the constraint  $M \geq \alpha C_1$ , which applies for the social planner, shall be achieved in the private economy through direct trade controls. In addition, in the decentralized solution the central bank will not have access to the private holdings  $M^*$  of foreign exchange.

Before formally solving this problem, an intuitive treatment is again useful. Suppose the social planner has made an optimal savings decision (i.e., chosen  $\dot{F}^*$ ), and then faces the budget constraint  $C_1 + C_2 = L - \dot{F}^*$  shown as  $BB$  in Figure 4. If at a point in time the foreign exchange holdings  $F^*$  are large, the transactions constraint  $F^* \geq \alpha C_2$  may be illustrated as  $SS$  which is not binding. In this case consumption would occur at  $P$ , and the social marginal rate of substitution along the indifference curve  $U$  would equal the ratio of international prices.

However, if the economy's foreign exchange holdings are small, then the transactions constraint may be illustrated by  $S'S'$  in Figure 4, and the available consumption set for the social planner is the shaded polygon  $OS'QB$ . The optimal consumption point would be  $Q$ , and the social marginal rate of substitution would differ from international prices. At the point  $Q$ , less of the importable good ( $C_2$ ) is consumed than in the absence of the transactions constraint on foreign exchange.

I shall now show that it is *optimal* for the social planner to deplete foreign exchange holdings to the point such as  $Q$ , where the relative marginal utility of consuming the importable exceeds its international price. This result is intuitively understood by first considering the transactions constraint  $S'S'$  in Figure 4, which would just permit the economy to consume at  $P$ . A slight reduction in foreign exchange holdings beyond this point would bring a gain from consumption of the importable. However, the loss to the economy by forcing the marginal rate of substitution to differ from international prices is initially of the second-order of smalls. Thus, starting at  $P$  the social planner would choose to deplete foreign exchange holdings further, moving the economy to a point such as  $Q$ . This behavior is formally analyzed as follows.

The optimality conditions for problem (11) are given by

$$(12) \quad U_1 = \mu, \quad U_2 = \mu + \alpha\lambda, \quad \dot{\mu} = \rho\mu - \lambda,$$

where  $\mu$  is the shadow price of foreign exchange and  $\lambda \geq 0$  is the Lagrange multiplier for the constraint  $F^* \geq \alpha C_2$ .<sup>9</sup> If this foreign exchange constraint is not binding, then  $\lambda = 0$  and conditions (12) imply that consumption of both goods falls at the exponential rate  $\rho/\sigma$ , with  $U_1 = U_2$ . When the foreign exchange constraint is binding, however, then  $\lambda > 0$  so  $U_2 > U_1$ , indicating that the social planner shifts consumption towards the export good 1 to economize on imports and

foreign exchange requirements. Indeed, in the long run,  $\dot{\mu} = 0$ , so  $\lambda = \rho\mu$  and  $U_2/U_1 = 1 + \alpha\rho$ , indicating a long-run divergence between the marginal rate of substitution and international price ratio.

The long-run formula  $U_2/U_1 = 1 + \alpha\rho$  can be readily understood. The marginal benefit from consuming a unit of the importable good 2, relative to good 1, is  $U_2/U_1$ . The marginal cost is its price of unity *plus* the cost of accumulating foreign exchange needed to satisfy the transactions constraint  $F^* \geq \alpha C_2$ . To consume one unit of the importable good,  $\alpha$  units of foreign exchange must be accumulated, which is possible by delaying consumption of the export good. The cost of delaying consumption is simply the discount rate. Thus, the marginal benefit of consuming the importable good equals its marginal cost of  $1 + \alpha\rho$ .

Next, it should be determined when the foreign exchange constraint  $F^* \geq \alpha C_2$  is binding:

LEMMA 2: *In the social optimum, the foreign exchange constraint is (not) binding according as  $C_1 + C_2 > (<) \beta_2 L$ , where  $\beta_2 \equiv 1/(1 - \gamma_2 \alpha \rho / \sigma)$ , and  $\gamma_2$  is the marginal and average propensity to consume good 2.*

The proof of this lemma follows by noting that when the foreign exchange constraint is binding we have  $\dot{F}^* = \alpha \dot{C}_2 = L - C_1 - C_2$ , and so

$$(13) \quad \dot{C}_2/C_2 = -(1/\alpha\gamma_2)[1 - L/(C_1 + C_2)]$$

The first point at which the foreign exchange constraint becomes binding is found by setting (13) equal to  $-\rho/\sigma$ , which is the rate of change of consumption without the constraint. Lemma 2 is thus obtained. Let us assume that  $0 < \gamma_2 < 1$ , and it follows that  $\beta_1 > \beta_2 > 1$ .

The socially optimal consumption path is shown as  $DEFG$  in Figure 2. I shall henceforth let  $T_1$  denote the time at which the consumer becomes illiquid (i.e.,  $(C_1 + C_2) = \beta_1 L$ ) along the optimal consumption path, and let  $T_2$  denote the time at which the social foreign exchange constraint  $F^* \geq \alpha C_2$  becomes binding along this path. Between times 0 and

<sup>9</sup>The Hamiltonian is  $H = U(C_1, C_2) + \lambda(F^* - \alpha C_2) + \mu(L - C_1 - C_2)$ , with optimality conditions  $\partial H / \partial C_i = 0$ ,  $i = 1, 2$ , and  $\dot{\mu} = \rho\mu - \partial H / \partial F^*$ .

$T_2$  the optimal consumption of both goods falls at the exponential rate  $\rho/\sigma$ , along the path  $DF$  in Figure 2. After  $T_2$  consumption,  $C_2$  falls at the slower rate given by (13), along the path  $FG$ . After the foreign exchange constraint is binding the relative marginal utility of consuming the importable exceeds its international price. In the following section I shall investigate methods to decentralize this social optimum.

#### IV. Policies to Obtain the Optimum

Let us consider several properties of the social optimum. For times beyond  $T_2$  in Figure 2, the social foreign exchange constraint is binding so that  $F^* = \alpha C_2$ . However, from the consumer's problem solved in Section I we also know that  $M^* = \alpha C_2$  for times beyond  $T_1$ . Since total foreign exchange  $F^*$  is defined as private holdings  $M^*$  plus reserves  $R^*$ , it follows that *government reserves are exhausted at time  $T_2$  and beyond*. That is, any policy leading to the social optimum will allow government reserves to be run down to zero at time  $T_2$ , and afterwards the official market will simply finance flow transactions in foreign exchange. The value of consumption exceeds labor income at time  $T_2$  and beyond, implying a balance of trade deficit, and the foreign exchange needed to finance imports is obtained from exports plus a reduction in the consumer's holdings of  $M^*$ .

Whenever the social foreign exchange constraint is not binding (i.e.,  $F^* > \alpha C_2$ ), then the marginal rate of substitution should equal the ratio of international prices to obtain the optimum. In this case, equal import tariffs and export subsidies could be used to reduce consumption through a real balance effect. When the social foreign exchange constraint is binding, however, the import tariff should exceed the export subsidy. The level of tariff and subsidy needed to reduce consumption to the socially optimal level also depends on the exchange rate. If the domestic currency is devalued through a discrete anticipated change or a crawling peg, then the required level of trade controls is lower.

The social optimum can be decentralized through a variety of policies, which I now examine in detail.

#### A. Direct Trade Controls

Let  $p_i$  denote the domestic price of good  $i$ ,  $i = 1, 2$ , so  $(p_1 - 1)$  is the export subsidy and  $(p_2 - 1)$  is the import tariff. Let us assume that tariffs on imported items are paid in the domestic currency. Then the transactions constraints (1) become

$$(14) \quad M \geq \alpha p_1 C_1 + \alpha (p_2 - 1) C_2,$$

$$M^* \geq \alpha C_2.$$

The difference between tariff revenues and subsidy payments are redistributed to (or collected from) the consumer as lump sum transfers. It is clear from (14) that raising the export subsidy or import tariff increases the amount of domestic currency needed to satisfy the transactions constraints, and therefore prevents this wealth from being spent on future consumption. In this way, raising the tariff or subsidy exerts a real balance effect on consumption.

The pattern of direct trade controls needed to support the social optimum is summarized as follows (the times  $T_1$  and  $T_2$  are defined following Lemma 2, and shown in Figure 2):

**PROPOSITION 1:** *The social optimum can be achieved by an import tariff and export subsidy satisfying:*

- (a) *for  $0 \leq t \leq T_1$  the tariff and subsidy are equal and constant;*
- (b) *for  $T_1 < t \leq T_2$  the tariff and subsidy are equal and rise gradually so that consumption continues to fall at the exponential rate  $\rho/\sigma$ ;*
- (c) *at  $T_2$  the tariff and subsidy are at a level that ensures that government reserves are exhausted;*
- (d) *for  $t > T_2$  the tariff rises above the subsidy, and in the long run, the price ratio approaches  $p_2/p_1 = 1 + \alpha p$ .*

Proposition 1 is explained as follows.<sup>10</sup> Over the range  $0 \leq t \leq T_1$  the private and socially optimal consumption of both goods falls at the rate  $\rho/\sigma$ . Then the tariff and subsidy are only used to exert a real balance effect on consumption. For  $T_1 < t \leq T_2$  the

<sup>10</sup> Formal proofs of this and other propositions are contained in my working paper, available on request.

consumer is illiquid, so private consumption would begin to fall at a rate slower than  $\rho/\sigma$  (as described following Lemma 1). However, the social foreign exchange constraint is not yet binding, so the government should intervene with a *rising* tariff and subsidy to ensure that consumption continues to fall at the rate  $\rho/\sigma$ . This range illustrates that government intervention is needed when the private transactions constraints are binding but the social constraint is not.

At time  $T_2$  the equal tariff and subsidy, denoted by  $p$ , will satisfy

$$(15) \quad M_0 - R_0^* = \alpha p C_1 + \alpha(p-1)C_2,$$

which states that domestic money demand equals  $M_0 - R_0^*$ . Thus, the reduction of the consumer's domestic money stock from  $M_0$  to this level implies that exactly  $R_0^*$  foreign exchange has been purchased from the central bank, depleting reserves. After time  $T_2$  the social foreign exchange constraint is binding, implying that the social planner shifts consumption towards the exportable to economize on imports and foreign exchange requirements. This shift in consumption is decentralized through the import tariff rising above the export subsidy. In the previous section it was found that the socially optimal ratio of marginal utilities approaches  $1 + \alpha\rho$  in the long run, implying the same ratio of domestic prices.

The pattern of trade controls described by Proposition 1 are numerically illustrated in Table 1. A discount rate of 5 percent per year is used, or 0.41 percent per month. From the *World Development Report 1981* (Table 15) the average ratio of international reserves to monthly imports for low-income countries is 2.8 in 1979, so  $\alpha = 2.8$  is chosen.<sup>11</sup> The marginal and average propensity to spend on the importable ( $\gamma_2$ ) is set at a relatively high value of 0.5. A Cobb-Douglas

utility function is used, and I consider the cases where the utility function is homogeneous of degree 0.1 ( $\sigma = 0.9$ ) and degree 0.9 ( $\sigma = 0.1$ ). In the latter case, the utility function nearly exhibits constant returns to scale, and assets are spent on consumption at a rapid rate.<sup>12</sup>

Let us suppose that initial holdings of domestic money are  $M_0 = 300$  while  $L = 100$ , so under *laissez-faire* the consumer would demand  $M_0 - \alpha\gamma_1 L = 160$  units of foreign exchange from the central bank. However, reserves are only one-half as much,  $R_0^* = 80$ . We can compute that the unanticipated devaluation needed to restore balance of payments equilibrium is  $x = 1.36$  or 36 percent.<sup>13</sup> Let us also suppose that the initial consumer holdings of foreign money are  $M_0^* = 300$ , so the total foreign exchange available to a social planner is  $F_0^* = 380$ . This information permits us to compute the times  $T_1$  and  $T_2$  along the social optimum, for varying values of  $\sigma$ .

The direct trade controls needed to obtain the social optimum are reported in Table 1, Part A. The optimum is achieved by initially setting an import tariff and export subsidy of 27.8 percent, with  $\sigma = 0.9$ . This constant level is held until the consumer becomes illiquid at  $T_1$ , and is then gradually increased to reach 28.1 percent at  $T_2$ . After this time the tariff rate rises above the subsidy, and in the long run their ratio is  $1 + \alpha\rho = 1.0115$  with the assumed parameter values. For other reasonable values of  $\alpha$  and  $\rho$  the difference between the long-run rates would still be small. For  $\sigma = 0.1$  the times  $T_1$  and  $T_2$  are recomputed, leading to different values of the trade controls along the adjustment path. However, the qualitative behavior of the trade controls in this case is the same as before:

<sup>11</sup>This calculation of  $\alpha$  is justified by interpreting  $M^*$  as claims by the representative consumer on foreign exchange reserves of the central bank. Also, McKinnon and Donald Mathieson (1981, p. 5) report that the ratio of domestic  $M_2$  to monthly GNP is 2.4 for typical Latin American economies, and 2.88 for Asia. So  $\alpha = 2.8$  appears consistent with the domestic transactions constraint, as well as the foreign.

<sup>12</sup>The value  $\sigma = 0.1$  is somewhat smaller than is supported by empirical evidence. Thus, the parameter  $-\sigma$  can be interpreted as the "expenditure elasticity of the marginal utility of income," and Ragnar Frisch (1959) conjectured it would lie in the range  $(-10, -0.1)$  with lower values applying to poorer countries. Subsequent estimates summarized in Alan Brown and Angus Deaton (1972, p. 1206) have established a range  $(-5, -0.5)$ , while in my model,  $-\sigma$  is restricted to the range  $(-1, 0)$ .

<sup>13</sup>This exchange rate is computed from the formula  $(M_0/x) - \alpha\gamma_1 L = R_0^*$ .

TABLE 1

$\sigma$		Initial Values	Values at $T_1$	Values at $T_2$	Long-Run Values	$T_1$ (months)	$T_2$
<b>A. Direct Trade Controls<sup>a</sup></b>

	Export						
	Subsidy	0	11.5	13.8	16.7		

<sup>a</sup>The tariff and subsidy rates are shown in percent.

<sup>b</sup>In this case foreign exchange reserves of the central bank are not drained until after 3.6 months, at which time an import tariff of 10.1 percent is applied.

the tariff and subsidy are constant and equal between times 0 and  $T_1$ , rise gradually to  $T_2$ , and after this point the tariff exceeds the subsidy to reflect the binding social foreign exchange constraint. The long-run optimal rates for the tariff and subsidy are independent of  $\sigma$ .

#### B. Anticipated Devaluation and Direct Trade Controls

A second method to obtain the social optimum is through a devaluation that is anticipated, combined with trade controls to correct the distorting effect of the currency flight on consumption. Thus, in Section II.B I argued that prior to the devaluation the central bank reserves would be drained and a floating, black market exchange rate established. This floating rate depreciates at the exponential rate  $\rho/\sigma$ , which implies that the consumer holds less domestic money and decreases consumption of the exportable to where  $U_1/U_2 = 1 + \alpha\rho/\sigma$ . To correct this dis-

tortion in consumption and achieve the social optimum, the following policy can be used:

**PROPOSITION 2:** *The social optimum can be achieved by an anticipated devaluation at time  $T' = T_1$  and trade controls satisfying:*

(a) *during the period before the devaluation, when central bank reserves are drained, an import tariff of  $(\alpha\rho/\sigma)/(1 + \alpha\rho/\sigma)$  is used;*

(b) *at  $T' = T_1$  the import tariff and export subsidy are both set at  $\alpha\rho/\sigma$ , and remain equal while rising until time  $T_2$ ;*

(c) *for  $t > T_2$  the tariff and subsidy are used as described in Proposition 1.*

Proposition 2 is explained as follows.<sup>14</sup> When the black market exchange rate is de-

<sup>14</sup>I have chosen to have the official devaluation occur at time  $T_1$  for convenience. This timing implies that the central bank will have to satisfy some demand for

preciating, the consumer shifts asset holdings towards foreign exchange, and the import tariff described in (a) is needed to offset the incentive to consume the foreign good. Immediately after the devaluation occurs, the tariff and subsidy should be equalized, but they cannot be set at zero for the following reason. To ensure that consumption follows the social optimum for  $0 \leq t \leq T_1$ , the relevant "price" of each good should be constant. Since  $\alpha$  units of domestic money must be held per unit consumption of good 1 its price equals  $p_1$  plus the loss through exchange rate depreciation, giving  $\pi = p_1(1 + \alpha \dot{x}/x)$  as the magnitude which must be constant. Thus, when the black market depreciation is reduced from  $\alpha\rho/\sigma$  to zero at the official devaluation, the nominal price of good 1 is correspondingly increased so that  $\pi$  is constant. To ensure that the consumption path chosen by the consumer coincides with the social optimum for  $T_1 < t \leq T_2$ , the tariff and subsidy should rise as described in Proposition 1. Beyond  $T_2$  the tariff exceeds the subsidy, and in the long run their ratio is  $p_2/p_1 = (1 + \alpha\rho)$ .

The appropriate devaluation and trade controls are numerically illustrated in Table 1, Part B, where an economy is considered with the same parameter values as in Section IV.A. The unanticipated devaluation needed to restore balance of payments equilibrium is 36 percent. With  $\sigma = 0.9$ , central bank reserves are drained immediately and the black market exchange rate jumps from unity to 1.33, thereafter depreciating at the exponential rate  $\rho/\sigma = 0.46$  percent. An import tariff of 1.26 percent is needed to offset the incentive to hoard foreign exchange and shift consumption towards the importable. At time  $T' = T_1$  the black market rate equals the official exchange rate of 1.52, which then remain constant. The official devaluation of

52 percent exceeds the unanticipated devaluation since consumers are now holding a minimum amount of domestic money. It follows that a greater devaluation is needed to achieve balance of payments equilibrium. At  $T_1$  the tariff and subsidy are adjusted slightly to 1.28 percent and rise to 1.45 percent at time  $T_2$ ; beyond this point the tariff exceeds the subsidy.

With  $\sigma = 0.1$ , initial consumption of good 1 is higher than before, requiring larger holdings of domestic money and therefore less demand for foreign exchange. In this case, government reserves are drained only after consumption of good 1 and domestic money holdings have been suitably reduced, which occurs in 3.6 months. For  $0 \leq t \leq 3.6$  the tariff and subsidy are zero. When reserves are drained the black market exchange rate begins to depreciate at the rate  $\rho/\sigma = 4.1$  percent. An import tariff of 10.1 percent is then required to offset the distorting effect on consumption. At  $T_1$ , the black market rate equals the official exchange rate of 1.16, and the tariff-cum-subsidy are adjusted to 11.5 percent. For  $T_1 \leq t \leq T_2$ , the tariff and subsidies rates rise somewhat, and after  $T_2$ , the tariff exceeds the subsidy. The relatively high level of these trade controls imply that the official devaluation of 16 percent is sufficient to achieve balance of payments equilibrium.

The advantage of this policy over just using direct trade controls is that, in reality, trade controls may lead to some resource cost beyond that captured in our model. Anne Krueger (1974) has emphasized the substantial "rent-seeking" costs associated with trade and foreign exchange quotas, while Bhagwati and T. N. Srinivasan (1980) have suggested that these costs can apply to tariffs as well. In the presence of such costs, the anticipated devaluation-cum-trade control option would be preferred to only using trade controls. However, it seems plausible that in reality the currency flight caused by a devaluation may also cause greater inefficiency than captured in our model. This consideration leads us to consider a third option for obtaining the social optimum: direct trade controls which are gradually reduced using a crawling peg devaluation.

foreign exchange between  $T_1$  and  $T_2$ , and therefore withhold a minimal level of reserves before exchange controls are imposed. For the two cases shown in Table 1, the level of withheld reserves are 0.46 and 5.05 with  $\sigma$  equal to 0.9 and 0.1, respectively, as compared with initial central bank reserves of 80.

### C. Direct Trade Controls and Crawling Peg

With an exchange rate of  $x$ , the transactions constraints (16) become

$$(14') \quad M/x \geq \alpha p_1 C_1 + \alpha(p_2 - 1)C_2,$$

$$M^* \geq \alpha C_2,$$

where  $p_i$  is the foreign currency price of good  $i$ ,  $i=1,2$ , inclusive of the tariff and subsidy rates. It is clear from (14') that higher values of  $x$  obtained through exchange rate devaluation can be used to replace that tariff and subsidy, while keeping the transactions constraint binding. When the exchange rate devalues through a crawling peg, the consumer shifts asset holdings towards foreign money and consumes more of the imported good, as occurred under the black market devaluation. Offsetting trade controls are then needed to retain the social optimum, as indicated in the following policy:

**PROPOSITION 3:** *The social optimum can be achieved by a crawling peg devaluation beginning at time  $T_3 > T_2$  and direct trade controls satisfying:*

(a) *up to time  $T_3$  the tariff and subsidy are applied as in Proposition 1;*

(b) *for  $t \geq T_3$  a crawling peg is adopted and that the tariff rises further above the export subsidy. As the exchange rate devalues, the tariff and subsidy are correspondingly reduced.*

(c) *The crawling peg is eliminated when a chosen level  $\bar{x}$  has been reached and  $\dot{x}=0$ , after which the exchange rate is constant. By choosing  $\bar{x}$  suitably high the tariff and subsidy can be made as low as desired, subject to the long-run relation  $p_2/p_1 = 1 + \alpha\rho$ .*

In the proof of Proposition 3 I derive a family of paths that the exchange rate must follow to support the social optimum. The initial choice of  $\dot{x}(T_3)$  can be made by the government, and corresponding to each choice is a unique path for the exchange rate. Let  $\bar{x}$  denote the maximum value of the exchange rate obtained along this path, which occurs at  $\dot{x}=0$ . When  $\bar{x}$  is reached the crawling peg is eliminated. Then it can be

shown that  $\bar{x}$  can be made as high as desired by suitable choice of  $\dot{x}(T_3) > 0$ . It follows that the tariff and subsidy can be made as low as desired, subject to the long-run relation  $p_1/p_2 = 1 + \alpha\rho$ .

The policies described in Propositions 1, 2, and 3 each support the same social optimum, so the choice between them must rest on considerations outside the model. I argued above that direct controls may involve "rent-seeking" costs, and that currency flight may lead to significant inefficiency beyond that captured in the model. In that case the crawling peg option would be preferred, since currency flight is avoided while the trade controls used are temporary. The only drawback to the crawling peg option is that the tariff and subsidy would need to be frequently reduced to exactly achieve the social optimum, while in practice the level of such trade controls may be inflexible.

### V. Discussion and Conclusions

In a series of pioneering papers, Helpman and Razin have analyzed "cash-in-advance" constraints in a discrete time trade model. They find that with complete markets these constraints are neutral and do not cause any inefficiency; see especially Helpman (1981b) who shows that the Pareto optimum is preserved. In contrast, I have found three reasons for using trade controls:

1) an equal import tariff and export subsidy will lower consumption and reduce the balance of payments deficit without causing currency flight;

2) a depreciation causes consumers to shift asset holdings towards foreign money and therefore purchase more of the importable;

3) private consumers and the social planner face different transactions constraints.

The third reason above is due to *incomplete markets*, that is, I have assumed that this country's currency is not traded on international markets and also that consumers cannot shift wealth across time through bond markets. It follows that at times the consumer is illiquid, while at other times the

social planner is constrained in foreign exchange. Resolving the difference between these private and social constraints is a rationale for government intervention.

However, the first and second reasons listed above are not due to incomplete markets, but rather, are due to *real balance effects*. That is, a devaluation or uniform tariff-cum-subsidy will reduce the real value of domestic money and lower consumption, but the real balance effect of a devaluation can be avoided by holding the foreign currency. Thus, anticipated devaluations cause a nonneutral change in desired asset holdings and consumption patterns. A fundamental point that should be recognized is that the *transactions constraints in the basic model of Helpman and Razin are neutral because real balance effects are absent*.

That is, Helpman and Razin suppose that in the beginning of a period each consumer receives wages, dividends, and government transfers in cash, which are then allocated between purchases of bonds and consumption goods in that period or carried over to the next. It is shown that with positive nominal interest rates no cash balances are carried across periods (Helpman, 1981b; Helpman and Razin, 1982b). It follows that prices and the exchange rate can jump from one period to the next with no real effects, since the real balances of all consumers are zero. The only exception occurs with respect to *initial* holdings of domestic and foreign bonds, whose real values are affected by price movements in the first period. However, changes in the real values of initial assets only cause an income transfer across countries and do not result in inefficiency.

In modifications of the basic model, real balance effects occur and exchange rate movements are nonneutral. Thus, in Helpman and Razin (1982a), capital markets are incomplete and prices are uncertain, so money is held across periods and real balance effects occur. A precautionary role for money also arises in Stockman (1980) and Svensson, where anticipated devaluations have a nonneutral effect on consumption. Nonneutrality of the exchange rate regime is observed in David Aschauer and Jeremy Greenwood

(1983) where labor supply is endogenous and wage payments are lagged one period. A similar time pattern in the payments of dividends is assumed in Helpman and Razin (1984) and the earlier, autarky model of Stockman (1981), and in both cases inefficiency can arise depending on the nominal interest rate. Introducing real balance effects has been facilitated in my model through the use of continuous time cash-in-advance constraints, which ensure that money balances are strictly positive. As these examples make clear, real balance effects can be an important source of nonneutrality of exchange rate movements.

This paper differs in spirit, but should be complementary to, analyses of the inefficiency of exchange control regimes as in Bhagwati (1978) and Krueger (1978). Thus, recognizing that the extensive systems of quotas and trade restrictions that exist in many developing countries are nonoptimal, I have tried to determine why these countries do not simply devalue. The reason I have identified is that anticipated devaluations will cause currency flight, which imposes a welfare cost on society. Thus, to control the balance of payments and obtain the social optimum, a more sophisticated policy is needed, and I identified three such policies: direct trade controls which are permanently applied; an anticipated devaluation causing currency flight, combined with direct trade controls to offset the speculation; and direct trade controls which are gradually eliminated through a crawling peg devaluation.

Since all these policies support the same social optimum, the choice between them rests on considerations outside of our model. In many cases it seems that the third option would be preferred: a uniform tariff-cum-subsidy applied initially to control the balance of payment, and then gradually reduced by a crawling peg and adjusted to nonuniform (with the tariff exceeding the subsidy) reflecting the binding social foreign exchange constraint. Elements of this policy have been used in various countries, and overall it seems to be a considerable improvement over existing systems of exchange controls or the dictum to simply devalue.

# Optimal Wage Indexation, Foreign Exchange Intervention, and Monetary Policy

By JOSHUA AIZENMAN AND JACOB A. FRENKEL\*

This paper deals with the design of optimal monetary policy and with the interaction between the optimal degrees of wage indexation and foreign exchange intervention. Recent studies of wage indexation in the closed economy have established that the optimal degree of wage indexation depends on the characteristics of the stochastic disturbances that affect the economy. In many of these studies, specifically in those that have adopted the analytical framework originated by Jo Anna Gray (1976), labor markets are characterized by the existence of nominal contracts that result in some stickiness of nominal wages. In these studies, indexation is intended to reduce the undesirable consequences of the stickiness of wages. Subsequent analyses of the optimal degree of wage indexation examined the implications of alternative assumptions about the determinants of employment in disequilibrium situations, as well as the rationale for the existence

of nominal contracts that yield sticky wages (see, for example, Robert Barro, 1977; Stanley Fischer, 1977a, b; Gray, 1978; Alex Cukierman, 1980; Edi Karni, 1983).

The analysis of optimal foreign exchange intervention, on the other hand, focused initially on the choice between a completely fixed and a completely flexible exchange rate system. Subsequent examinations of the same question have shifted the focus from the problem of choice between the two extreme exchange rate regimes to the problem of the optimal degree of exchange rate flexibility. Thus, the focus has shifted towards finding the *optimal mix* of the fixed and the flexible exchange rate regimes. Consequently, that analysis has attempted to determine the optimal degree of exchange rate management (see our 1982 article and the references therein).

More recently it has been recognized that the optimal degree of wage indexation depends on the prevailing exchange rate regime. Thus, Robert Flood and Nancy Marion (1982) showed that a small open economy with fixed exchange rates should adopt a policy of complete wage indexation whereas an economy with flexible exchange rates should adopt a policy of partial wage indexation. This analysis was extended by Aizenman (1985) who showed that, under flexible exchange rates, the optimal degree of wage indexation rises with the degree of openness of the economy as measured by the relative size of the traded goods sector. On the other hand, some authors have recognized that the choice between fixed and flexible exchange rate regimes depends on labor market conventions (for example, see Jagdeep Bhandari, 1982). Specifically, it has been argued that the degree of wage indexation determines the relative efficiency of macroeconomic policies under alternative exchange rate regimes and, therefore, the choice between the two re-

gimes should depend on whether wages are indexed or not (for example, see Jeffrey Sachs, 1980, and Richard Marston, 1982a).

Common to these studies is the characteristic that the economy is either searching for the optimal degree of wage indexation under the assumption that the exchange rate regime (being fixed or flexible) is exogenously given, or that it is choosing between fixed and flexible exchange rate regimes under the assumption that the degree of wage indexation is exogenously given. The point of departure of this paper is the notion that the optimal degrees of wage indexation and exchange rate intervention are interrelated and are mutually and simultaneously determined. Therefore, in our analytical framework the choice of the optimal degrees of wage indexation and exchange rate intervention emerges as the outcome of a joint-optimization problem. This joint-optimization outcome is shown to be a component of the solution to the broader problem of the design of optimal monetary policy.

The interdependence among monetary policy, foreign exchange intervention, and labor market conditions, as characterized by the degree of wage indexation, has been clearly recognized by policymakers and has been viewed as an important constraint on the conduct of policy particularly in highly inflationary countries. And yet, except for few exceptions like Stephen Turnovsky (1983a), the question of the formal interaction between the optimal degrees of indexation and foreign exchange intervention, especially within the context of the design of optimal monetary policy has not received attention in the theoretical literature. This question is addressed in the subsequent sections.

Section I describes the building blocks of the model, including the determination of output and employment, the specification of wage contracts, and the determination of prices and exchange rates. One of the key characteristics of the model is the menu of the stochastic shocks. It is assumed that the economy is subject to stochastic shocks to productivity, to foreign prices, to purchasing power parities, to the rate of interest, and to the money supply. Much of the analysis de-

pends, therefore, on the relative magnitudes of these shocks, as well as on the information set that individuals are assumed to possess.

Our analysis assumes that, due to cost of negotiations, nominal wages are precontracted and real wages adjust according to a simple indexation formula that links the change in wages to the observed change in the price level. The level of employment in turn is assumed to be determined by firms according to their demand for labor. This specification of labor market conventions may result in discrepancies between the *realized* levels of real wages and employment and the *equilibrium* levels obtained when labor markets clear continuously without friction. The goal of policies is to minimize the welfare loss associated with such discrepancies.

Section II contains an analysis of the objective function which is given a formal justification in the Appendix. In Section III, we specify the optimal money supply process and derive the optimal set of policy rules that should govern the conduct of monetary policy. These policy rules determine the optimal response of monetary policy to changes in exchange rates, interest rates, and foreign prices. One of the key results is that the adoption of the optimal set of policy rules results in the complete elimination of the welfare cost. Thus, optimal policies nullify the distortions arising from the simple indexation rule and from the existence of nominal contracts. Since optimal policies succeed in the elimination of the distortions, critical issues concerning the nature of contracts and the implications of specific assumptions about disequilibrium positions become inconsequential. We then proceed to examine the interdependence between the design of optimal monetary policy rules and the optimal degree of wage indexation. This section concludes with the proposition that the number of independent indicators that govern a policy aiming at the elimination of a distortion, must equal the number of independent sources of information that influence the determination of the undistorted equilibrium. Thus, it is shown that with a sufficient number of indicators for monetary policy, there may be no need to introduce wage indexa-

tion. By the same token it is also shown that an economy that is not able to choose freely an exchange rate regime can still eliminate the welfare loss by supplementing the (constrained) monetary policy with an optimal rule for wage indexation.

Section IV examines the implications of the optimal policies on the means and the variances of money and output. In Section V, we apply our analytical framework to second-best situations in which policy cannot be used optimally. In this context we determine the optimal indexation coefficient for an economy that is constrained to follow a given exchange rate regime, and determine the optimal degree of exchange rate intervention for an economy that is constrained to follow a given wage indexation rule. For both of these cases we show the dependence of the (constrained) optimal policies on the details of the stochastic disturbances that affect the economy, and we compute the values of the loss function that result from the adoption of various policies.

### I. The Model

The model that we use has several building blocks. These include the specification of output and employment, the specification of the wage rule and the determination of prices and exchange rates. In this section we outline the structure of the model.

#### A. Output and Employment

Let the production function be

$$(1) \log Y_t = \log B + \beta \log L_t + \mu_t, \quad 0 \leq \beta \leq 1,$$

where  $Y_t$ ,  $L_t$ , and  $\mu_t$  denote, respectively, the level of output, the input of labor, and a productivity shock, at time  $t$ . The productivity shock  $\mu_t$  is assumed to be distributed normally with a zero mean and a known variance  $\sigma_\mu^2$ . Within each period the realized value of the productivity shock is not known, and the expectations concerning the realized value of  $\mu_t$  are formed on the basis of the information that is available during the period. Throughout the analysis we assume that at each point in time *all* prices and rates

of interest are known. The *conditional* expectation of  $\mu_t$ , as based on the information available at period  $t$ , is denoted by  $E_t(\mu_t)$ .

Producers are assumed to maximize the expected value of profits subject to the available information. Thus, in their demand for labor, producers are assumed to equate the real wage to the expected marginal product of labor. Expressed logarithmically, this equality implies that

$$(2) \log(W/P)_t = \log \beta B - (1 - \beta) \log L_t + E_t(\mu_t),$$

where  $W$  and  $P$  denote the nominal wage and the price level, respectively. From equation (2), the demand for labor is

$$(3) \log L_t^d = [-\log(W/P)_t + \log \beta B + E_t(\mu_t)] / (1 - \beta),$$

where  $L_t^d$  designates the demand for labor.<sup>1</sup> In order to simplify notation, we suppress from here on the subscript  $t$ . Thus, unless stated otherwise, the conditional expectation of the productivity shock  $E_t(\mu_t)$  will be denoted  $E(\mu)$ , and will also be referred to as the perceived productivity shock. Assuming that employment is determined by the demand for labor, we substitute equation (3) into (1) and obtain the level of output that

<sup>1</sup>Formally, the firm facing a given real wage is assumed to demand labor so as to maximize the expected value of profits conditional on the available information. Thus

$$\max_{L_t} E_t \{ BL_t^\beta e^{\mu_t} - (W/P)_t L_t \}.$$

The resulting demand for labor (expressed logarithmically) is

$$\log L_t^d = [\log \beta B - \log(W/P)_t + \log E_t(e^{\mu_t})] / (1 - \beta),$$

and using the approximation  $\log E_t(e^{\mu_t}) \approx E_t(\mu_t)$  we obtain equation (3). The same approximation, that is valid for small values of the variance and the realization of the stochastic shock, is also used in the derivation of the expected value of the marginal product of labor in equation (2).

corresponds to the employment of labor:

$$(4) \quad \log Y = \log B + \beta\sigma [\log P - \log W \\ + \log \beta B + E(\mu)] + \mu,$$

where  $\sigma \equiv 1/(1-\beta)$ . Equation (4) specifies the *stochastic* supply of output that is obtained when the value of the productivity shock is  $\mu$ . The corresponding *deterministic* level of output is

$$(4') \quad \log Y_0 = \log B \\ + \beta\sigma (\log P_0 - \log W_0 + \log \beta B),$$

where  $P_0$  and  $W_0$  denote the market-clearing price level and nominal wage that are obtained in the absence of stochastic shocks.

For the subsequent analysis it is useful to denote by lowercase letters the percentage discrepancy of a variable from the value that it obtains in the absence of shocks. Thus,  $x \equiv \log X - \log X_0$ . Accordingly, from equations (4) and (4') we obtain

$$(5) \quad y = \beta\sigma [p - w + E(\mu)] + \mu.$$

Equation (5) shows that the percentage deviation of output from its deterministic level depends on the percentage deviation of the real wage from its deterministic value, on the perceived productivity shock,  $E(\mu)$ , as well as on the realized productivity shock,  $\mu$ . Our subsequent analysis specifies the determinants of  $w$ ,  $p$ , and  $E(\mu)$ .

### B. The Wage Rule

It is assumed that due to costs of negotiations, nominal wages are set according to the following simple, time-invariant, indexation rule:

$$(6) \quad \log W_t = \log W_0 + b(\log P_t - \log P_0).$$

Equation (6) specifies the wage at period  $t$  as a function of  $W_0$ , the equilibrium wage that would have prevailed if shocks were zero, and the percentage deviation of the price

from its nonstochastic value.<sup>2</sup> In equation (6),  $b$  designates an indexation parameter. When  $b=1$ , wages are fully indexed to the rate of inflation and the real wage is rigid. When  $b=0$ , nominal wages are rigid. From equation (6) it follows that  $w = bp$ . Substituting  $bp$  for  $w$  in equation (5) yields

$$(7) \quad y = \beta\sigma [(1-b)p + E(\mu)] + \mu.$$

Equation (7), which may be viewed as an aggregate supply function, expresses the supply of output as a function of the price  $p$ , as well as the perceived and realized productivity shocks. The dependence of the supply on the price depends in turn on the coefficient of indexation  $b$ ; a higher indexation coefficient results in a weaker dependence of output on the price.

### C. The Price Level and the Exchange Rate

The domestic price level is assumed to be linked to the foreign price through purchasing power parity. Let the foreign price be

$$(8) \quad \log P'_t = \log \bar{P} + \chi_t,$$

where a prime denotes a foreign variable and a bar over a variable denotes the value of its fixed component. In equation (8),  $\chi_t$  denotes the stochastic component of the foreign price which is assumed to be distributed normally with zero mean and a fixed known variance. The domestic price is linked to the foreign price according to

$$(9) \quad \log P_t = \log S_t + \log P'_t,$$

where  $S_t$  denotes the exchange rate (the price of foreign currency in terms of domestic

<sup>2</sup>It is assumed that the initial nominal wage is set at the level  $W_0$ . This assumption is justified in the Appendix. Our specification of the indexation rule corresponds to a wage rule that is widely used in practice, and its main virtue is simplicity. Much of our subsequent analysis aims to demonstrate that with proper monetary policy, which is governed by time-invariant policy rules, this simplicity need not yield suboptimal outcomes.

currency). Using (8) for  $\log P_t'$  yields

$$(10) \quad \log P_t = \log S_t + \log \bar{P}' + \chi_t.$$

In principle, the random component of  $P_t$  may also include stochastic deviations from the purchasing power parity relation of equation (9). When all shocks are zero, the domestic price is

$$(10') \quad \log P_0 = \log S_0 + \log \bar{P}',$$

and subtracting (10') from (10) yields

$$(11) \quad p = s + \chi.$$

where, as before, we suppress the time subscripts.

The formulation in equation (11) links the domestic price to the exchange rate and the stochastic shock  $\chi$ . In order to determine the level of prices we need to incorporate monetary considerations. The equilibrium price level and exchange rates can be derived from the conditions of money market equilibrium. Let the demand for money be

$$(12) \quad \log M_t^d = \log K + \log P_t + \log Y_t - \alpha i_t,$$

where  $M$  denotes nominal balances and  $i$  denotes the nominal rate of interest. The nominal rate of interest in turn is linked to the foreign rate of interest,  $i'$ . Arbitrage by investors, who are assumed to be risk neutral, assures that uncovered interest parity holds:<sup>3</sup>

$$(13) \quad i_t = i'_t + E_t(\log S_{t+1} - \log S_t),$$

where  $E_t \log S_{t+1}$  denotes the expected exchange rate for period  $t+1$  based on the information available at period  $t$ . The foreign rate of interest is also subject to a random shock,  $\rho$ , which is distributed normally with zero mean and a fixed known

variance. Thus,

$$(14) \quad i'_t = \bar{i}' + \rho_t.$$

In specifying the money supply process, we assume that the monetary authority takes account of the relevant *information* conveyed by a specific set of independent indicators. Since at each point in time prices and interest rates are known, we assume that the supply of nominal balances adjusts in response to the three independent indicators  $s_t$ ,  $\rho_t$ , and  $\chi_t$ , according to

$$(15) \quad \log M_t^s = \log \bar{M} + \delta_t - \gamma s_t - \tau \rho_t - \xi \chi_t$$

where  $\delta$  (which is assumed to be distributed normally with zero mean and a fixed known variance) denotes a random shock to the money supply process. In equation (15),  $\gamma$  denotes the elasticity of the money supply with respect to  $s$ —the deviation of the exchange rate from its deterministic value,  $\tau$  denotes the elasticity of the money supply with respect to  $\rho$ —the stochastic shock to the foreign rate of interest, and  $\xi$  denotes the elasticity of the money supply with respect to  $\chi$ —the stochastic shock to foreign prices. In the subsequent analysis of the money supply rule, we justify the choice of this set of indicators and determine the optimal values of the time-invariant coefficients  $\gamma$ ,  $\tau$ , and  $\xi$ .

Equilibrium in the money market requires that

$$(16) \quad \log K + \log P_t + \log Y_t - \alpha i_t = \log \bar{M} + \delta_t - \gamma s_t - \tau \rho_t - \xi \chi_t,$$

and, when all shocks are zero, money market equilibrium yields<sup>4</sup>

<sup>4</sup> It is relevant to note that from equations (13)–(14),

$$i - \bar{i}' = \rho + E_t \log S_{t+1} - \log S_t,$$

and the specification of the stochastic shocks implies that  $E_t \log S_{t+1} = \log S_0$ . The implicit assumption underlying this formulation is that  $E_t \log S_{t+1}$  is not influenced by the observed price. Our assumption about the absence of trend allows us to focus on the properties of the stationary equilibrium for which the current

<sup>3</sup> More precisely, when prices are stochastic, uncovered interest parity holds only as an approximation due to Jensen's inequality. This approximation is valid for small values of the variance of the stochastic shock to prices; see Frenkel and Assaf Razin (1980).

$$(16') \quad \log K + \log P_0 + \log Y_0 - \alpha \bar{i}' = \log \bar{M}.$$

Subtracting (16') from (16) and omitting the time subscript yields

$$(17) \quad p + y - \alpha(i - \bar{i}') = \delta - \gamma s - \tau p - \xi \chi.$$

Substituting equations (7) and (11) for  $y$  and  $p$  and using the fact that the domestic rate of interest (from equations (13)–(14)) is  $i' + \rho - s$ , we obtain

$$(18) \quad \lambda(s + \chi) + \beta \sigma E(\mu) + \mu - \alpha(\rho - s) \\ = \delta - \gamma s - \tau p - \xi \chi,$$

where  $\lambda \equiv [1 + \beta \sigma(1 - b)]$ .

In equation (18),  $\lambda$  denotes the elasticity of nominal income (and thereby of the reduced-form demand for money) with respect to prices. As may be seen, the magnitude of  $\lambda$  depends on the size of the indexation coefficient  $b$ . When wage indexation is complete (i.e., when  $b = 1$ ), price changes do not alter output and  $\lambda = 1$ . When  $b$  is less than unity, a rise in the price alters real wages by  $(1 - b)$  and, therefore, it also affects money demand through changing real output by  $\beta \sigma(1 - b)$ . From equation (18) it follows that the equilibrium percentage change in the exchange rate is

$$(19) \quad s = \frac{(\alpha - \tau)\rho - (\mu - \delta) - \beta \sigma E(\mu) - (\lambda + \xi)\chi}{\lambda + \alpha + \gamma}.$$

As is evident from equation (19), when  $\gamma = 0$  the exchange rate is fully flexible, and when  $\gamma = \infty$ ,  $s = 0$  and the exchange rate is fixed. Between these two extremes there is a wide range of intermediate exchange rate regimes.

Recalling that  $p = s + \chi$ , and using equation (19) we can express the price as

$$(20) \quad p = \chi + \frac{(\alpha - \tau)\rho - (\mu - \delta) - \beta \sigma E(\mu) - (\lambda + \xi)\chi}{\lambda + \alpha + \gamma}.$$

As may be seen, the price depends on the realization of the stochastic shocks, on the perceived value of the real shock  $E(\mu)$ , on the coefficient of wage indexation  $b$ , on the coefficient of foreign exchange intervention  $\gamma$ , and on the other coefficients which govern monetary policy.

The value of  $E(\mu)$  that is consistent with the information structure and with the requirement of rational expectations reflects the information set that is available to decision makers. We assume that at each point in time individuals observe the current values of the price  $p$ , the exchange rate  $s$ , and the rates of interest  $i$  and  $i'$ , but they cannot observe *directly* the stochastic shocks. Since our analysis does not deal with issues arising from asymmetric information, we also assume that individuals know the policy rules. The available information set can be used by individuals in order to infer the values of some of the shocks. For example, the observed values of  $p$  and  $s$  imply the value of  $\chi$  (from equation (11)), and the observed value of  $i'$  implies the value of  $\rho$  (from equation (14)). While individuals do not possess knowledge about the values of the real productivity shock  $\mu$ , and the money supply shock  $\delta$ , their knowledge of the values of  $p$ ,  $\chi$ , and  $\rho$  along with their knowledge of the coefficient of wage indexation  $b$ , and of the coefficients of the money supply function  $\gamma$ ,  $\tau$ , and  $\xi$ , implies, from equation (20), a value for  $(\mu - \delta)$ . The value of  $(\mu - \delta)$  may be viewed as the informational content of the price  $p$ . The assumption of rational expectations implies that the optimal forecast of  $\mu$  reflects an efficient use of this information. Thus, the value of  $E(\mu)$  may be computed from a regression of  $\mu$  on  $(\mu - \delta)$ . The ordinary least squares estimate of the real shock that is obtained through this procedure is  $E(\mu) = \psi(\mu - \delta)$ , where  $\psi \equiv \text{cov}(\mu, \mu - \delta) / \sigma_{(\mu - \delta)}^2$ , and where  $\sigma_{(\mu - \delta)}^2$  de-

values of the stochastic shocks do not affect the expectations about future values of the variables. The specification of equation (16') also embodies the assumption that the equilibrium is unique. The choice of the unique equilibrium is consistent with the criterion suggested by Bennett McCallum (1983). On the issue of uniqueness, see Guillermo Calvo (1979), and Turnovsky (1983b).

notes the variance of  $(\mu - \delta)$ .<sup>5</sup> When the shocks are independent of each other the regression coefficient becomes  $\psi = \sigma_\mu^2 / (\sigma_\mu^2 + \sigma_\delta^2)$ , where the variance of a variable,  $x$ , is denoted by  $\sigma_x^2$  (to be distinguished from the production parameter  $\sigma \equiv 1/(1 - \beta)$ ).

Finally, substituting the estimates of the real shock  $E(\mu)$  into equation (20), we obtain

$$(21) \quad p = \frac{(\alpha - \tau)\rho + (\alpha + \gamma - \xi)\chi - (1 + \beta\sigma\psi)(\mu - \delta)}{\lambda + \alpha + \gamma}$$

This solution for  $p$  can be substituted into equation (7) to yield an expression for the aggregate supply as a function of the stochastic structure of the shocks, the coefficient of wage indexation  $b$  (that is embodied in the value of  $\lambda$ ), and the various coefficients which govern policy. In order to determine the optimal values of these coefficients we turn next to an analysis of the objective function.

## II. The Objective Function

The foregoing analysis determined the level of output,  $y$  (or more precisely the percentage deviation of output from the level that would have prevailed in the absence of shocks) under the assumption that employment is determined exclusively by the demand for labor (equation (3)). The resultant disequilibrium in the labor market induces welfare cost. We assume that the policy goal is to minimize this welfare cost by choosing the optimal values of the coefficient of indexation and of the coefficients governing monetary policy.

In order to compute the welfare cost, we compute the level of employment  $\tilde{L}$  that

would have prevailed under conditions of full clearance of labor markets. We then compare  $\tilde{L}$  with the actual level of employment  $L$ , and compute the welfare cost that is associated with a discrepancy between  $\tilde{L}$  and  $L$ .<sup>6</sup>

Let the supply of labor be

$$(22) \quad \log L_t^s = \log A + \varepsilon \log (W/P)_t,$$

where  $\varepsilon$  denotes the elasticity of labor supply. Equating the supply of labor, equation (22), with the demand for labor, equation (3), yields the *equilibrium* level of employment,  $\log \tilde{L}$ , where

$$(23) \quad \log \tilde{L} = \log A + \varepsilon [(\sigma(E(\mu) + \log \beta B) - \log A) / (\sigma + \varepsilon)],$$

and subtracting from (23) the equilibrium level of employment that would have prevailed in the absence of shocks, we obtain

$$(24) \quad \tilde{l} = \varepsilon \sigma E(\mu) / (\sigma + \varepsilon).$$

Actual employment, however, may not adjust to clear labor markets; rather, it is governed by the assumptions that labor is demand determined and wages are determined by the indexation rule. Subtracting from the actual supply of output (equation (1)) the supply that would have obtained in the absence of shocks, yields

$$(25) \quad y = \beta l + \mu,$$

and thus, employment (or more precisely the percentage deviation of employment from the level that would have prevailed in the absence of shocks) is

$$(26) \quad l = (y - \mu) / \beta.$$

<sup>5</sup>This procedure for determining  $E(\mu)$  may be viewed as a short cut to the more lengthy computation following the undetermined coefficients method. An analogous short cut is adopted in Matthew Canzoneri, Dale Henderson, and Kenneth Rogoff (1983) in the context of an analysis of the informational content of interest rates.

<sup>6</sup>A formal derivation of the loss function is presented in the Appendix in terms of utility maximization. In what follows we provide a somewhat less formal exposition in terms of consumers' and producers' surplus.

By using equation (5) for the value of  $y$ ,  $l$  can be written as

$$(26') \quad l = -\sigma[(w - p) - E(\mu)],$$

and, therefore, the discrepancy (in percentage terms) between equilibrium and actual employment is

$$(27) \quad l - \bar{l} = \sigma \left[ -(w - p) + \frac{\sigma}{\sigma + \varepsilon} E(\mu) \right].$$

In order to compute the welfare loss associated with this discrepancy, we need to multiply it by one-half of the difference between the demand and the supply prices at the actual employment level. This procedure amounts to a computation of the area of a triangle representing the welfare cost in terms of the loss of consumers' and producers' surplus. From the demand for and the supply of labor, these demand and supply prices (or more precisely the percentage changes thereof) are, respectively,

$$(28) \quad (w - p)^d = -(l - \bar{l})/\sigma + (\widetilde{w - p})$$

$$(29) \quad (w - p)^s = (l - \bar{l})/\varepsilon + (\widetilde{w - p}),$$

and the percentage welfare cost of suboptimal employment is therefore

$$(30) \quad \frac{\sigma^2}{2} \left( \frac{1}{\varepsilon} + \frac{1}{\sigma} \right) \left[ -(w - p) + \frac{\sigma E(\mu)}{\sigma + \varepsilon} \right]^2.$$

As is clear from equation (30), once we omit the irrelevant constants, minimizing the expected welfare loss on the basis of the information available at period  $t - 1$  amounts to minimizing the loss function  $H$ :

$$(31) \quad H = E \left[ \left\{ -(w - p) + \left( \sigma / (\sigma + \varepsilon) \right) E(\mu) \right\}^2 \middle| I_{t-1} \right],$$

where  $I_{t-1}$  denotes the information set available at period  $t - 1$ .<sup>7</sup>

<sup>7</sup>It is relevant to note that the formulation of the objective function in terms of a minimization of the welfare cost of the distortions in the labor market is

### III. Optimal Policies

In order to find the optimal values of the coefficient of indexation and the other feedback coefficients that govern policy, we substitute into equation (31) the indexation rule  $w = bp$ , the forecasting rule  $E(\mu) = \psi(\mu - \delta)$ , and the solution for  $p$  from equation (21), and obtain the following loss function:

$$(32) \quad H = E \left[ \left\{ \phi \theta + \left( \sigma / (\sigma + \varepsilon) \right) \psi(\mu - \delta) \right\}^2 \middle| I_{t-1} \right],$$

where

$$(33) \quad \begin{cases} \phi \equiv ((1 - b)/(\lambda + \alpha + \gamma)) \\ \theta \equiv (\alpha - \tau)\rho + (\alpha + \gamma - \xi)\chi \\ \quad - (1 + \beta\sigma\psi)(\mu - \delta). \end{cases}$$

In equation (32),  $\phi\theta$  denotes the (percentage) change in the real wage  $(1 - b)p$ .

In interpreting the loss function (32), it is useful to note that the term  $\psi(\mu - \delta)$  de-

equivalent to the more conventional (but somewhat less informative) formulation of minimizing the expected squared discrepancy of output,  $y$ , from the equilibrium level,  $\bar{y}$ , obtained with full market clearing (see Aizenman, 1983). This equivalence becomes evident by noting that since  $(y - \bar{y}) = \beta(l - \bar{l})$ ,  $E(y - \bar{y})^2 = \beta^2 E(l - \bar{l})^2$ . In order to obtain the welfare loss in units of output we need to multiply equation (30) by the equilibrium real wage bill,  $(W/P)\bar{L}$ . The resulting quantity is the same as equation (A8) in the Appendix. Our focus on the labor market in the computation of the welfare cost presumes that other markets are undistorted. An explicit incorporation of this assumption would require that monetary policies at home and abroad generate the optimal rate of inflation. With this interpretation, our formulation of the stochastic shock to the money supply would be viewed as a random deviation from the deterministic trend reflecting the optimal rate of inflation. Equation (31) presumes that the authorities aim to minimize the expectations of the welfare loss on the basis of the information set available at period  $t - 1$ . The alternative specification which minimizes the expected welfare loss on the basis of the currently available information yields policy coefficients that are not time-invariant. Since, as will be seen below, the optimal time-invariant coefficients eliminate the welfare loss, the choice between the two procedures might reflect the excess costs associated with state-dependent rule.

notes the private sectors' optimal forecast of the real shock,  $\mu$ , and its product with  $\sigma/(\sigma + \varepsilon)$  measures therefore the *equilibrium* change in real wages that would occur under an optimal use of information. On the other hand, the *actual* change in real wages that results from the adoption of specific policy rules is  $-\phi\theta$ . The expected squared discrepancy between the two magnitudes, that is, the variance of the error in the determination of actual real wages, entails welfare loss which is measured by the loss function  $H$ . By inspecting the value of  $\theta$  in equation (33), it is clear that in order to minimize the loss function (32), we need to set

$$(34) \quad \tau^* = \alpha;$$

$$(35) \quad \xi^* = \alpha + \gamma,$$

where  $\tau^*$  and  $\xi^*$  designate the optimal values of  $\tau$  and  $\xi$ . Assuming that the values of  $\tau$  and  $\xi$  are set according to equations (34) and (35), the loss function (32) becomes

$$(32') \quad E \left\{ \left[ -\phi(1 + \beta\sigma\psi) + (\sigma/(\sigma + \varepsilon))\psi \right] (\mu - \delta) \right\}^2 | I_{t-1} \right\},$$

and it is evident that the value of  $\phi$  which equates (32') to zero is

$$(36) \quad \phi^* = \sigma\psi / [(\sigma + \varepsilon)(1 + \beta\sigma\psi)].$$

Finally, by equating the value of  $\phi^*$  with its definition in equation (33), we solve for the optimal value of  $\gamma$ :

$$(37) \quad \gamma^* = (1 - b)((\sigma + \varepsilon)/\sigma\psi)(1 + \beta\sigma\psi) - \alpha - \lambda,$$

and substituting  $1 + \beta\sigma(1 - b)$  for the value of  $\lambda$  yields

$$(37') \quad \gamma^* = (1 - b)[(\sigma + \varepsilon(1 + \beta\sigma\psi))/\sigma\psi] - (1 + \alpha).$$

Equations (34), (35), and (37') provide three restrictions on the values of the four policy coefficients  $\tau$ ,  $\xi$ ,  $\gamma$ , and  $b$ . As is

evident, this set of restrictions contains one degree of freedom. Since, however, the structure of the model implies that these restrictions are recursive, it follows that of the four policy coefficients,  $\tau$  is indispensable. The degree of freedom permits setting an arbitrary value to one of the coefficients in the triplet  $(b, \xi, \gamma)$ , while setting the other two at their optimal values. For example, if the indexation coefficient  $b$  is given exogenously, the restrictions in equations (34), (35), and (37') imply the optimal values of  $\tau$ ,  $\xi$ , and  $\gamma$ . This provides the rationale for the specification of the money supply process in equation (15). Adopting this optimal set of policy rules for the money supply process results in the *elimination* of the welfare loss.

Equation (37') also suggests that the optimal value of  $\gamma$  depends on the structural parameters of the economy (including the semi-elasticity of the demand for money ( $\alpha$ ), the elasticity of output with respect to labor input ( $\beta$ ), and the elasticity of the supply of labor ( $\varepsilon$ )); on the stochastic structure of the real and the monetary shocks (that govern the value of  $\psi$ ) and on the indexation coefficient  $b$ . Thus, for example, the higher the elasticity of the supply of labor, the larger becomes the optimal value of  $\gamma$ , that is, the larger becomes the desirability of greater fixity of exchange rates.

As is evident from equation (37'), around the optimum, there is a negative correlation between the value of  $\gamma^*$  and the (exogenously given) degree of wage indexation. Thus, an economy with a higher degree of wage indexation will find it optimal to increase the flexibility of exchange rates (reduce  $\gamma^*$ ). As the coefficient of wage indexation approaches unity, the degree of real wage rigidity increases, and the optimal value of  $\gamma^*$  approaches  $-(1 + \alpha)$ .<sup>8</sup> Furthermore,

<sup>8</sup>At the extreme, with full indexation, the optimal value of  $\gamma$  is undetermined. This may be verified by reference to the loss function in equations (32)-(33), where it is seen that when  $b = 1$ , the value of  $\phi$  is zero and, as a result, the value of the loss function is independent of  $\gamma$ . Intuitively, full indexation introduces real wage rigidity. Consequently, changes in the price level that can be brought about through changes in the exchange rate and that are influenced by the exchange rate

since from equation (35) the value of  $\xi^*$  depends linearly on  $\gamma^*$ , it also follows that a higher degree of wage indexation lowers the optimal degree to which monetary policy responds to  $\chi$  (the shocks to foreign prices).

The forgoing analysis also demonstrates that as long as the money supply responds optimally to  $s$ ,  $\rho$ , and  $\chi$ , which in the present case are the relevant sources of independent information that can be used to yield the market-clearing real wage, there is no need to introduce wage indexation. Thus, it was shown that when the degree of freedom provided by equations (34), (35), and (37) is used up by setting the indexation coefficient at an exogenously given level, the welfare loss can be eliminated by a proper choice of  $\gamma$ ,  $\tau$ , and  $\xi$ . If, on the other hand, the value of  $\gamma$  were given exogenously, then the welfare loss could still be eliminated by supplementing the optimal values of  $\tau$  and  $\xi$  in the money supply process with an optimal rule of wage indexation. From equation (37') the optimal value of  $b$  for an exogenously given value of  $\gamma$  is

$$(38) \quad b^* = 1 - (1 + \alpha + \gamma) / \left[ (\sigma_s^2 / \sigma_\mu^2) (1 + (\varepsilon / \sigma)) + 1 + \varepsilon \right].$$

The dependence of the value of  $b^*$  on the magnitudes of the key parameters is qualitatively similar to the dependence of  $\gamma^*$  on these parameters. Thus

$$\frac{\partial b^*}{\partial \psi} < 0, \quad \frac{\partial b^*}{\partial \varepsilon} > 0, \quad \frac{\partial b^*}{\partial \gamma} < 0, \quad \frac{\partial b^*}{\partial \beta} < 0.$$

Accordingly, a rise in the relative variance of the real shock, a rise in the elasticity of output with respect to labor input, and a rise in the degree of fixity of exchange rates result in a lower optimal value of the indexation coefficient, whereas a rise in the elastic-

ity of labor supply raises the optimal degree of wage indexation. It is relevant to note that by setting  $\gamma = 0$ , the optimal indexation coefficient becomes

$$(38') \quad b_c^* = 1 - (1 + \alpha) / \left[ (\sigma_s^2 / \sigma_\mu^2) (1 + (\varepsilon / \sigma)) + 1 + \varepsilon \right],$$

where  $b_c^*$  denotes the closed-economy value. This is indeed the optimal indexation coefficient that is derived in Aizenman's (1983) closed-economy model.<sup>9</sup>

The economic intuition underlying the redundancy of one of the coefficients in the triplet  $(\gamma, \xi, b)$  is implicit in the structure of the model. Since the rate of interest appears only in the demand for money, the only way of eliminating the impact of an interest rate shock on the loss function is by setting  $\tau^* = \alpha$  as in equation (34). No other policy rule can eliminate the impact of an interest rate shock. In contrast, the rest of the shocks manifest themselves through the price level and, together with the given nominal wage, they impact on the real wage which is the source of the welfare loss. Since from equation (21),  $\gamma$  and  $\xi$  influence the price level whereas the wage indexation coefficient influences both the price level and the nominal wage, they all alter the real wage directly. Given the nature of the shocks we need only three independent indicators.<sup>10</sup> Therefore, it is sufficient to

<sup>9</sup>The intuition underlying this result is that the optimal policy-response coefficients for the open economy ensure that the price level effects arising from the shocks  $\rho$  and  $\chi$  (that originate from the openness of the economy) are offset by setting  $\tau = \alpha$  and  $\alpha + \gamma = \xi$ . Thus, at the optimum, policy succeeds in creating an outcome that is equivalent to the one generated by  $\rho = \chi = 0$ . Since in the closed economy  $\rho = \chi = \gamma = 0$ , we only need to substitute  $\gamma = 0$  in equation (38) to obtain the closed-economy result. Alternatively,  $b_c^*$  can be obtained directly from the loss function (32)–(33) by noting that when the economy is closed,  $\rho = \chi = \gamma = 0$ ,  $\theta = -(1 + \beta\sigma\psi)(\mu - \delta)$ , and the value of  $b$  that eliminates the welfare loss is  $b_c^*$  as in (38').

<sup>10</sup>An analogous redundancy proposition is developed in Canzoneri, Henderson, and Rogoff in connection with the usage of the information contained in nominal interest rates. It is noteworthy that our objective function presumes that the only policy objective is the

regime will be inconsequential since, due to the rigidity of real wages, they will induce equiproportionate changes in nominal wages. Obviously, when real wages are completely rigid, monetary policy cannot eliminate labor market distortions arising from disequilibrium real wages.

use in addition to  $\tau$ , which is in this model an indispensable policy rule, any other pair from the triplet  $(\gamma, \xi, b)$ .

The examples analyzed above illustrated the substitutability between exchange rate flexibility and wage indexation under the assumptions either  $\gamma$  or  $b$  are set exogenously, and that  $\tau$  and  $\xi$ —the coefficients of response to interest rate shocks  $\rho$ , and to foreign price shocks  $\chi$ —are set optimally. Suppose now that the authorities do not adopt a policy response to  $\chi$ . Under these circumstances, again  $\tau^* = \alpha$  and, since  $\xi = 0$ , it follows from equation (35) that the optimal value of  $\gamma$  is  $-\alpha$ . Thus, when  $\xi = 0$  the solution for the optimal exchange rate regime is unique and, in contrast with the case described by equation (37'), the value of  $\gamma^*$  is independent of the deterministic and the stochastic structure of the economy.

The optimal value of the indexation coefficient corresponding to that case can be found from equation (38). Substituting  $\gamma = -\alpha$  yields

$$(38'') \quad b^* \Big|_{\substack{\tau^* = \alpha \\ \gamma^* = -\alpha}} \\ = 1 - 1 / \left[ \left( \sigma_\delta^2 / \sigma_\mu^2 (1 + (\varepsilon / \sigma)) + 1 + \varepsilon \right) \right].$$

A comparison of equation (38'') with (38') reveals that

$$(39) \quad b^* \Big|_{\substack{\tau^* = \alpha \\ \gamma^* = -\alpha}} > b_c^*.$$

That is, when in the open economy  $\tau$ ,  $\gamma$ , and  $b$  are set at their optimal values, the resultant wage indexation coefficient is larger than the corresponding closed-economy optimal indexation coefficient.<sup>11</sup>

elimination of distortions. If, in addition, the policy-maker wishes to reduce the variance of prices, then the redundant coefficient could be employed in the attainment of that target. In the present model, however, the assumption concerning the utility function does not provide an obvious rationale for reducing the variance of prices.

<sup>11</sup> This result reflects our specification of the nature of the shocks by which the openness of the economy does not increase the exposure to foreign real shocks. In

The incorporation of the various shocks as components of the policy rules governing the money supply process may serve to supplement Tinbergen's theorem concerning the relation between targets and instruments of economic policy. In our case the single "target" for economic policy is the elimination of a distortion to the real wage. This single target can be attained by means of the single instrument of monetary policy. Our analysis shows that the single instrument is capable of attaining the target only if it is triggered by a sufficient number of independent indicators. This number of independent indicators for the policy rules must equal the number of independent sources of information that influence the determination of the undistorted real wage. This perspective on the concept of optimal policy was illustrated in our model in terms of the characteristics of the money supply process. It does, however, have relevance for a wider range of policies including the characteristics of fiscal spending.

Finally, we have argued that the optimal policy could follow a sophisticated money supply rule that is triggered by a sufficient number of independent indicators. Alternatively, the optimal policy could follow a sophisticated wage indexation formula that is not limited to respond only to changes in the price level. Following the general principle, such an indexation formula will be optimal only if it responds to a sufficient number of signals and, as was argued before, the number of such independent indicators must equal the number of the independent sources of information that matter in determining the market-clearing real wage.<sup>12</sup> The choice among the alternatives of a sophisticated money supply rule, a sophisticated wage in-

principle the relative importance of real shocks may be higher for the open economy if, for example, it faces shocks to the price of imported raw materials. In that case the optimal indexation coefficient may be lower than  $b_c^*$ .

<sup>12</sup> For illustrations of the optimal design of sophisticated indexation formula in the context of a closed economy, see Fischer (1977a), Karni, and our 1985 paper.

dexation formula, or any other sophisticated set of policies is likely to be governed by the relative costs and complexities associated with each alternative. Such costs may reflect the difficulties of prompt implementations of alternative policy responses. The choice among alternative policies is also likely to be influenced by external constraints (like the rules of the IMF on foreign exchange intervention) and domestic institutional constraints (like the relative strength of the monetary authority and labor unions). Therefore, the actual choice of policy is likely to differ across different countries. The possibility that the optimal choice may differ across countries may be relevant for the design of IMF programs. Furthermore, from the global perspective, such possible international differences of optimal intervention rules need to be reconciled with each other in order to ensure consistency of the international monetary system.

#### IV. The Optimal Levels and Variability of Money and Output

In this section we assume that the optimal policies have been adopted and we examine the implications of these optimal policies on the means and the variances of the money supply and output.

##### A. The Optimal Money Supply

The money supply function was specified in equation (15) ( $m = \delta - \gamma s - \tau p - \xi \chi$ ). Substituting the optimal values of  $\tau$  and  $\xi$  from equations (34)–(35), and recalling that  $p = s + \chi$ , yields

$$(40) \quad m = \delta - \gamma p - \alpha(\rho + \chi).$$

Substituting (37') for the optimal value of  $\gamma$ , collecting terms and recalling that  $\rho + \chi - p = i - i'$  yields the optimal money supply:

$$(40') \quad m^* = \delta - [(1-b)((\sigma + \epsilon(1 + \beta\sigma\psi)) / \sigma\psi) - 1] p - \alpha(i - i').$$

Equation (40') which may be interpreted as a reduced-form optimal money supply,

expresses the dependence of  $m^*$  on the price and on the rate of interest. As may be seen, a rise in the rate of interest triggers a reduction in the money supply. The optimal reduction in the money supply aims to restore money market equilibrium and thereby to neutralize the effect of the change in the rate of interest on the price and, through it, on the real wage. Therefore, the (semi) elasticity of  $m^*$  with respect to  $i$  is  $-\alpha$ , and changes in  $m^*$  exactly match and offset changes in the demand for money.<sup>13</sup> The response of the optimal money supply to changes in  $p$  is more involved since it depends on the stochastic structure and on the coefficient of indexation.

In order to obtain further understanding of the characteristics of the optimal money supply, it is convenient to express  $m^*$  as a function of the stochastic shocks. For this purpose we note from equation (21) that with optimal policies the optimal price is<sup>14</sup>

$$(21') \quad p^* = \frac{-\sigma\psi}{(1-b)(\sigma + \epsilon)}(\mu - \delta).$$

Substituting equations (37') and (21') for the optimal values of  $\gamma$  and  $p$  into equation (40) and collecting terms yields

$$(40'') \quad m^* = -g\psi\delta + (1 + g\psi)\mu - \alpha(\rho + \chi),$$

$$\text{where} \quad g = \frac{\sigma}{\sigma + \epsilon} \left[ \beta\epsilon - \frac{1 + \alpha}{1 - b} \right].$$

<sup>13</sup> This property of the optimal money supply reflects the assumption that the rate of interest does not affect the real equilibrium of the economy. In a more elaborate framework the rate of interest may affect the real equilibrium through altering the supply of labor or through its impact on relative commodity prices.

<sup>14</sup> It may be shown that at the optimum the variance of the price is

$$\sigma_p^2 = (\sigma/(\sigma + \epsilon))^2 \psi \sigma_\mu^2 / (1 - b)^2.$$

In general,  $\sigma_p^2 = \sigma_s^2 + \sigma_\chi^2 + 2\text{cov}(s, \chi)$  and, since at the optimum under our assumptions  $\text{cov}(s, \chi) = -\sigma_\chi^2$ , it follows that  $\sigma_s^2 = \sigma_p^2 + \sigma_\chi^2$ , i.e., the variance of the exchange rate exceeds the variance of the price level.

The economic interpretation of (40'') is facilitated by substituting the perceived value of the real shock,  $E(\mu)$ , for  $\psi(\mu - \delta)$  and by rewriting (40'') as

$$m^* - \delta = (\mu - \delta) + gE(\mu) - \alpha(\rho + \chi),$$

where  $m^* - \delta$  denotes the optimal money supply net of the random component  $\delta$ . Thus,  $m^* - \delta$  is the part of the money supply that is attributed to the optimal policy rules. As may be seen, the parameter  $g$  is the elasticity of the optimal money supply with respect to the perceived value of the real shock. The sign of this elasticity depends on the coefficient of indexation and on the values of the structural parameters.

Using equation (40''), the variance of the optimal money supply can be written as

$$(41) \quad \sigma_{m^*}^2 = [1 + g(2 + g)\psi] \sigma_\mu^2 + \alpha^2 \sigma_{\rho+\chi}^2.$$

From equation (41) it is evident that a rise in the variance of  $\rho$ ,  $\chi$ , and  $\mu$  raises the variance of the optimal money supply while a rise in the variance of  $\delta$  exerts an ambiguous effect.

### B. Optimal Output

The level of output corresponding to the optimal policies is  $y^*$  which equals the level of output obtained with full market clearing. This level can be found from equation (24) and (25) or, alternatively, it can be found by substituting the optimal price from equation (21') into the aggregate supply in equation (7). Thus,

$$(42) \quad y^* = \frac{\beta\epsilon\sigma}{\sigma + \epsilon} \psi(\mu - \delta) + \mu.$$

From equation (42) it follows that at the optimum the variance of output is

$$(43) \quad \sigma_{y^*}^2 = \left[ 1 + \frac{\beta\epsilon\sigma}{\sigma + \epsilon} \psi \left( 2 + \frac{\beta\epsilon\sigma}{\sigma + \epsilon} \right) \right] \sigma_\mu^2.$$

As is evident, the variance of the optimal level of output depends positively on the variance of the real shock  $\sigma_\mu^2$ , and negatively on the variance of the monetary shock  $\sigma_\delta^2$ .

Since a rise in the variance of the real shock raises the value of  $\psi$ , its effect on the variance of optimal output is being magnified and the elasticity of  $\sigma_{y^*}^2$  with respect to  $\sigma_\mu^2$  exceeds unity.

### V. Constrained Optimization and Welfare

The analysis up to this point determined the optimal degrees of wage indexation and the optimal values of the response coefficients that govern monetary policy. The optimal values of the response coefficients were determined by minimizing the loss function. In this section we compute the values of the loss function that result from the adoption of various policy rules. This procedure enables us to compare the welfare loss that results from the imposition of alternative constraints on the degree of wage indexation, exchange rate intervention, and other policy instruments. The analysis also illustrates the more general proposition concerning the link between the information set and the number of independent response coefficients necessary for welfare maximization.

Using equations (32)–(33), the loss function can be written as

$$(44) \quad H = \phi^2 \sigma_\theta^2 - 2\phi(\sigma/(\sigma + \epsilon)) \times \psi(1 + \beta\sigma\psi) \sigma_{\mu-\delta}^2 + (\sigma^2 \psi^2 / (\sigma + \epsilon)^2) \sigma_{\mu-\delta}^2$$

$$\text{where } \sigma_\theta^2 = (\alpha - \tau)^2 \sigma_\rho^2 + (\alpha + \gamma - \xi)^2 \sigma_\chi^2 + (1 + \beta\sigma\psi)^2 \sigma_{\mu-\delta}^2.$$

We first consider the situation in which the only instrument of policy that can be set at its optimal level is the coefficient of wage indexation. In order to find the optimal value of the indexation coefficient, we note that in the loss function (44),  $b$  appears only in  $\phi$ ; therefore, minimization of  $H$  with respect to  $b$  is equivalent to minimization with respect to  $\phi$  (holding  $\gamma$  constant). This procedure yields the optimal value of  $\phi$ :

$$(45) \quad \phi^* = (\sigma/(\sigma + \epsilon))(1 + \beta\sigma\psi)(\sigma_\mu^2/\sigma_\theta^2),$$

By equating  $\phi^*$  with the definition of  $\phi$  in (33) we can obtain the optimal value of the indexation coefficient.

Substituting  $\phi^*$  for  $\phi$  in equation (44) and assuming that  $\xi = \tau = 0$ , the loss function becomes

$$(46) \quad H(b^*; \gamma) = \left( \sigma^2 \psi \sigma_\mu^2 / (\sigma + \varepsilon)^2 \right) \times \left[ \frac{\alpha^2 \sigma_\rho^2 + (\alpha + \gamma)^2 \sigma_\chi^2}{\alpha^2 \sigma_\rho^2 + (\alpha + \gamma)^2 \sigma_\chi^2 + (1 + \beta \sigma \psi)^2 \sigma_{\mu-\delta}^2} \right],$$

where  $H(b^*; \gamma)$  indicates that the loss function is evaluated under the condition that only the coefficient of wage indexation is set optimally, while the value of  $\gamma$  is set at an arbitrary level. When the exchange rate is fixed ( $\gamma = \infty$ ) the value of the loss function is

$$(46') \quad H(b^*, \gamma)|_{\gamma=\infty} = \left( \sigma^2 \psi \sigma_\mu^2 / (\sigma + \varepsilon)^2 \right),$$

and, when the exchange rate is flexible ( $\gamma = 0$ ) the value of the loss function is

$$(46'') \quad H(b^*, \gamma)|_{\gamma=0} = \left( \sigma^2 \psi \sigma_\mu^2 / (\sigma + \varepsilon)^2 \right) \times \left[ \frac{\alpha^2 (\sigma_\rho^2 + \sigma_\chi^2)}{\alpha^2 (\sigma_\rho^2 + \sigma_\chi^2) + (1 + \beta \sigma \psi)^2 \sigma_{\mu-\delta}^2} \right].$$

As is evident from comparison of equations (46') and (46''),

$$(47) \quad H(b^*, \gamma)|_{\gamma=\infty} \geq H(b^*, \gamma)|_{\gamma=0}.$$

Thus, except for extreme cases (like, for example, when there are no real shocks), the welfare loss for an economy for which only the wage indexation coefficient is set optimally is higher under fixed exchange rates than under flexible exchange rates. This result confirms the proposition established by Flood and Marion.

The forgoing analysis presumed that the value of  $\gamma$  is set at an arbitrary level that may not correspond to its optimal value. In order to obtain the optimal value of the coefficient of intervention in the foreign exchange market, we differentiate the loss func-

tion (44) with respect to  $\gamma$  and equate the derivative to zero:

$$(48) \quad \frac{\partial H}{\partial \phi} \frac{\partial \phi}{\partial \gamma} + 2(\alpha + \gamma - \xi) \sigma_\chi^2 \phi^2 = 0.$$

The assumption that the coefficient of wage indexation is set at its optimal value  $b^*$ , implies that at this point  $\partial H / \partial \phi = 0$  and, therefore, equation (48) implies that the optimal foreign exchange intervention coefficient is

$$(49) \quad \gamma^* = \xi - \alpha.$$

Substituting (49) into the loss function (44) and recalling that in the present stage of the analysis we have assumed that policy is constrained to set  $\xi = 0$ , yields

$$(50) \quad H(b^*, \gamma^*) = \left( \sigma^2 \psi \sigma_\mu^2 / (\sigma + \varepsilon)^2 \right) \times \left[ \frac{\alpha^2 \sigma_\rho^2}{\alpha^2 \sigma_\rho^2 + (1 + \beta \sigma \psi)^2 \sigma_{\mu-\delta}^2} \right],$$

where  $H(b^*, \gamma^*)$  indicates that the loss function is evaluated under the conditions that both wage indexation and exchange rate intervention are optimal. By subtracting equation (50) from (46) we obtain the marginal benefit from allowing optimal response to exchange rate changes. It can be shown that this marginal benefit is proportional to  $(\alpha + \gamma)^2 \sigma_\chi^2$ .

Equation (50) suggests that when  $\sigma_\rho^2 = 0$ ,  $H(b^*, \gamma^*) = 0$ . Thus, in this case, the optimal use of wage indexation and exchange rate intervention *eliminate* completely the welfare loss even though the value of  $\xi$  was constrained to equal zero. Likewise, inspection of equation (46) suggests that if both  $\sigma_\rho^2$  and  $\sigma_\chi^2$  are zero, as would be the case in a closed economy, then  $H(b^*) = 0$ . In this closed-economy case,  $b^* = b_c^*$  as in equation (38'), and the optimal use of the *single* instrument of wage indexation is capable of eliminating the welfare cost of labor market distortion.<sup>15</sup>

<sup>15</sup>A comparison between this result and that of Gray (1976) illustrates the role of the number of sources of

The economic intuition underlying these results can be stated in terms of the relation between the number of independent sources of information and the number of independent indicators governing policy rules. Two of the key assumptions underlying the model are that the level of employment is determined by the demand for labor and that real wages are adjusted according to an indexation formula that links the real wage *only* to the observed price level. The use of the price level in the adjustment of real wages as the only indicator to which the indexation rule applies may not permit an efficient use of the information that is available to economic agents. For example, in our model it is assumed that at each point in time individuals observe (or are able to infer without error) the shocks to prices  $\chi$ , the shocks to the rate of interest  $\rho$ , and the difference between the real and the monetary shocks,  $\mu - \delta$ . Adopting a single policy rule that links the real wage to the price level through the indexation coefficient may not use efficiently the more detailed information that is available in the open economy and that could be exploited in the adjustment of real wages.

---

information. In Gray's model there are two independent sources of information that are used in determining the equilibrium real wage. Therefore, the use of simple wage indexation *alone* does not eliminate the welfare loss. In contrast, when the present model is reduced to its closed-economy counterpart, there is only one independent source of relevant information (information about  $\mu - \delta$ ) and, therefore, the optimal use of the simple wage indexation rule eliminates the welfare loss. This discussion implies that if the magnitude of  $\mu$  were also known along with the knowledge of prices, interest rates, and the exchange rate, then the specification of the optimal money supply, that aims at eliminating the welfare loss, would include  $\mu$  as an additional indicator. In principle we could also introduce asymmetric information by which each individual firm observes their firm-specific shock but the aggregate economywide shock is not observable; for related specifications, see Flood-Hodrick and Marston-Turnovsky (1983b). It is important to emphasize that in our framework the welfare cost does not reflect assumptions concerning incomplete or asymmetric information. Rather, the information set is assumed to be equally shared among market participants and policymakers but, due to contracts, this shared information may not be immediately acted upon by market participants.

This is the reason for the proposition that, except for special cases,  $H(b^*, \gamma) > 0$ .

In equation (46), the value of the term in the squared brackets characterizes the quality of the use of information in the adjustment of real wages. When this term is zero, as would for example be the case when  $\sigma_p^2 = \sigma_\chi^2 = 0$ , then the information set is used most efficiently in the sense that the observed price provides all of the relevant information for determining the optimal adjustment of real wages. Under such circumstances, indeed, the optimal indexation coefficient  $b^*$  eliminates the welfare loss, as would be the case in the closed economy. In general, however, if  $\sigma_p^2$  or  $\sigma_\chi^2$  are positive, then the squared bracket term in equation (46) is positive, indicating that the adoption of a single policy indicator when there are more independent sources of information does not result in a market-clearing real wage and, therefore, does not eliminate the welfare loss. Another illustration of this argument is provided by equation (50) where it is assumed that the policy is governed by two independent indicators. Under such circumstances, if there are three independent sources of information (the observed values of  $s$ ,  $p$ , and  $\rho$ ), the adoption of the optimal values  $b^*$  and  $\gamma^*$  does not eliminate the welfare loss and  $H(b^*, \gamma^*) > 0$ . In contrast, if there were no shocks to the rate of interest, there would only be two independent sources of information ( $s$  and  $p$ ); in such a case the term in the squared brackets in equation (50) would be zero, indicating that the optimal response to the two indicators is capable of eliminating the welfare loss since it generates the market-clearing real wage.

The forgoing discussion dealt with the policies necessary for the elimination of the welfare loss arising from suboptimal real wages. The fundamental proposition, however, is more general. Policies can be designed to eliminate the welfare cost of distortions. The general principle developed by Tinbergen states that in order to attain  $n$  targets, economic policy must possess at least  $n$  independent instruments. Our application demonstrated that with the necessary number of instruments, the optimal policy will

succeed in attaining the targets only if the instruments are influenced by a sufficient number of independent indicators.<sup>16</sup> This sufficient number must equal the number of independent sources of information that influence the determination of the undistorted level of the targets.

## VI. Concluding Remarks

In this paper we have analyzed the relation between the optimal degrees of wage indexation and foreign exchange intervention. The optimal values of these policy instruments were obtained as components of the solution to the broader problem of the design of optimal monetary policy. The model used for the analysis was governed by the characteristics of the stochastic shocks that affect the economy and by the information set that individuals were assumed to possess.

Throughout the analysis the optimal policies are obtained with reference to an objective function that has the desirable property of possessing explicit welfare justification. It represents the welfare loss arising from the assumptions that employment is governed by the demand for labor, nominal wages are precontracted, and real wages are adjusted according to an indexation formula that links the real wage to the observed price. The use of the price level in the adjustment of real wages as the only indicator to which the indexation rule applies may not permit an efficient use of the information that is available to economic agents and that could be exploited in the adjustment of real wages. The loss function reflects the welfare cost associated with a discrepancy between the equilibrium change in real wages that would occur under an optimal use of information and the actual change in real wages that

results from labor market conventions and from the adoption of specific policy rules.

One of the key findings of the paper concerns the conditions under which the optimal policy, by minimizing the loss function, also *eliminates* the welfare cost. It was shown that if the number of independent indicators that govern policy is equal to the number of independent sources of information that are relevant for the determination of the market-clearing real wage, then the adoption of the optimal policy rules eliminates completely the welfare cost of labor market distortions. This proposition is important, since the elimination of the welfare cost implies that the optimal policies are capable of reproducing the equilibrium that would be obtained under the assumption that labor markets were cleared after the realization of the stochastic shocks. By reproducing that equilibrium, the optimal policies nullify the distortions that result from the assumption that, because of contracts, nominal wages are predetermined. When such an optimum obtains, the important issues concerning the implications of the assumption that employment is determined by the demand for labor, as raised by Cukierman, are inconsequential since, at the optimum, there is an equality between the demand and the supply of labor. Similarly, when the optimum obtains many of the critical issues concerning the conceptual difficulties associated with the existence of suboptimal contracts, as raised by Barro, are also inconsequential since, at the optimum, the contracts (along with the optimal policy) are optimal. In that sense the equilibrium which eliminates the welfare loss is analogous to the closed-economy equilibria that were analyzed by Karni and Aizenman (1983).

The principle underlying the determination of the optimal set of policy rules was illustrated in terms of the design of a sophisticated monetary policy. Alternatively, in situations where a sophisticated monetary policy is not feasible, analogous considerations could be incorporated into the design of a sophisticated wage indexation formula. As long as each independent source of information that is relevant for the determination

<sup>16</sup> The requirement that the indicators must be independent is reflected in our case by the exclusion of the price  $p$  from the set of indicators governing the supply of money. Clearly, of the triplet  $p, s, \chi$ , only two contain independent information that can be usefully exploited. Thus, of the three, we chose to include  $s$  and  $\chi$  in the set of indicators.

of the market-clearing real wage serves as an independent indicator for policy that is used optimally, the resulting equilibrium replicates the distortion-free equilibrium.

Our analysis showed that when wage indexation serves as one of the independent policy rules, then a rise in the variance of the real productivity shock and a rise in the elasticity of output with respect to labor input lower the optimal degree of wage indexation. On the other hand, a rise in the variance of the monetary shock and a rise in the elasticity of labor supply raise the optimal degree of wage indexation. It was also shown that when the degree of foreign exchange intervention is exogenously given, then, around the optimum, a rise in the degree of exchange rate flexibility raises the optimal degree of wage indexation. Likewise, when the degree of wage indexation is exogenously given, then, around the optimum, a higher degree of wage indexation raises the optimal degree of exchange rate flexibility.

We concluded our discussion with an examination of the consequences of departures from optimal policies. In this context we compared the welfare loss that results from the imposition of alternative constraints on the degree of wage indexation, on foreign exchange intervention and on the magnitudes of other policy coefficients.

One of the limitations of the analysis in this paper relates to the level of aggregation. We have assumed that there is one composite good which is internationally traded at a (stochastically) given world price. A useful extension would allow for a richer menu of commodities including those that are internationally tradable and those which are nontradable. The presence of nontradable goods would then relax some of the constraints that were imposed by the small country assumption. Owing to its relative size, the economy would still be a price taker in the world traded-goods market, but the relative price of its nontraded goods would be endogenously determined by market-clearing conditions. Such an extension should facilitate the distinction between mechanisms and policies that operate on the price level and those that operate on relative prices. It would allow for a distinction between the relative price of

traded goods—the external terms of trade—and the relative price of nontraded goods—the internal terms of trade (the real exchange rate)—and would facilitate an analysis of deviations from purchasing power parity. The introduction of nontraded goods should also permit an analysis of the influence of the degree of openness (as measured by the relative size of the traded-goods sector) on the optimal values of the coefficients that govern policy. Previous studies suggest that the degree of openness may play a significant role in influencing optimal policies (our 1982 paper and Aizenman, 1985). The broader menu of goods should also facilitate an analysis of the optimal indexation rules in the face of supply shocks (as in Marston and Turnovsky, 1983a), as well as an analysis of the proper price index that should be used in the indexation formula (as in Marston, 1982b, and in our 1985 article).

Another extension of the analysis would draw an explicit distinction between permanent and transitory shocks. In our specifications the stochastic disturbances were assumed to be independent of each other and to be drawn from a distribution with a constant variance and a zero mean. A more complete analysis would distinguish between permanent and transitory shocks and would incorporate the role of time preference; thereby, it would introduce dynamic considerations into the analysis of the optimal choice of policies.

It is relevant to note that the nature of labor contracts assumed in this paper was motivated by realism. Accordingly, we assumed that contracts specify the nominal wage whereas the level of output is determined by firms, and that the indexation formula is simple in that it adjusts wages to changes in the price level rather than to a complex set of variables. Our analysis does not attempt to contribute to the theory that explains this conventional form of labor contract (on this see Barro and Fischer, 1977b).

Finally, we define the equilibrium that replicates the performance of an economy in which labor markets clear without friction, as the social optimum. Implicit in this definition of the social optimum is the assumption

that individuals and firms are risk neutral since, in general (as shown by Costas Azariadis, 1978), when attitudes towards risk differ across economic agents, auction markets do not allocate risk efficiently and individuals find it advantageous to enter into long-term risk-sharing contracts. Our assumption, therefore, precludes rationalizing the existence of labor contracts in terms of the insurance function. Therefore, in this framework (as in Gray, 1978), the existence of contracts reflects the cost of negotiations.

## APPENDIX

### *The Derivation of the Objective Function*

In the two parts of this Appendix we provide a formal justification for the specification of the loss function.

*Part I:* Define by  $(\bar{W}/P)$  the equilibrium real wage that clears the labor market. This equilibrium value of the real wage clears the market for any given expected value of the real shock conditional on the available information. Since in equilibrium the real wage equals the expected marginal product of labor, the amount of labor,  $\bar{L}$ , that clears the labor market when the real wage is  $(\bar{W}/P)$  is defined by

$$(A1) \quad E[Y_L(\bar{L})|I_t] = (\bar{W}/P),$$

where  $I_t$  denotes the information set available at time  $t$ , and where  $Y_L(\bar{L})$  denotes the marginal product of labor evaluated at  $L = \bar{L}$ . For subsequent use it is convenient to define the function  $\bar{X}$  as the expected value of  $X$  conditional on the available information  $I_t$ . Thus, applying this notation to equation (A1) yields:

$$(A1') \quad \bar{Y}_L(\bar{L}) = (\bar{W}/P).$$

General equilibrium requires that the level of employment  $L$  be also consistent with the supply of labor that is supplied by utility-maximizing workers at the given real wage  $(\bar{W}/P)$ . To illustrate, let the utility func-

tion be

$$(A2) \quad u(C, L); \quad \partial u / \partial C > 0, \quad \partial u / \partial L < 0,$$

where  $C$  denotes the level of consumption and  $L$  denotes labor, that is, negative leisure. Maximization of the utility function subject to the technological constraint that production  $Y$  is governed by the production function  $Y = F(L)$ , and that, from the budget constraint in the absence of asset accumulation, the values of production and consumption must coincide, yields the desired supply of labor. In general equilibrium, with  $L = \bar{L}$ , the equilibrium level of utility is denoted by  $U(\bar{L})$ .

In practice, due to a precontracted nominal wage, the realized real wage may differ from its full equilibrium level. Since by assumption employment is demand determined, it follows that the actual level of employment,  $L$ , when the real wage differs from  $(\bar{W}/P)$ , differs from  $\bar{L}$  and, associated with this level of employment and production, the level of utility is  $U(L)$ .

The welfare cost of suboptimal employment is  $[U(\bar{L}) - U(L)]/\lambda$  where  $\lambda$  measures the marginal utility of income. Using Arnold Harberger's formulation (1971, equation 5') for the analysis of consumer's surplus, we expand the utility function in a Taylor series around the general equilibrium and omit third-order terms to obtain Harberger's expression for the approximation of the welfare loss:

$$(A3) \quad \Delta U / \lambda \approx \sum [P_i^0 \Delta C_i - \frac{1}{2} \Delta P_i \Delta C_i],$$

where  $\Delta C_i$  denotes the change in the rate of consumption of good  $i$ ,  $P_i^0$  denotes the equilibrium price of good  $i$ , and where  $\Delta P_i$  measures the discrepancy of the full equilibrium price from the actual price. In applying (A3) to the utility function assumed here, it is useful to decompose the expression into terms involving goods and those involving labor (or leisure). In our case, with a single (composite) commodity which is used as the numeraire, an application of Harberger's formula yields  $\Delta C$  as the welfare change associated with the change in the consumption of

that good. The same procedure is also applied to labor, which is the second argument in the utility function  $u(C, L)$ , and whose equilibrium price is  $-(\bar{W}/P)$ . For that component we obtain  $-(\bar{W}/P)\Delta L + \frac{1}{2}\Delta(\bar{W}/P)^s\Delta L$ , where the change in the real wage is measured along the supply of labor that reflects the utility function. Combining the expressions measuring the welfare cost of changes in consumption and labor yields (A4) as the welfare loss:

$$(A4) \quad \Delta U/\lambda \approx \Delta C - (\bar{W}/P)\Delta L + \frac{1}{2}\Delta(\bar{W}/P)^s\Delta L,$$

where  $\Delta L = \tilde{L} - L$ . In computing the value of the expression in (A4) we simplify the specification of the intertemporal budget constraint by specifying a temporal budget constraint according to which  $\Delta C = \Delta Y$  and, therefore, the value of  $\Delta C$  can be obtained by calculating  $\Delta Y$ . It is noteworthy, however, that in general, the values of expenditure and income in each period need not be equal to each other as long as there is equality between their discounted present values. With undistorted capital markets, however, the two formulations are equivalent as is known from the literature on the Ricardian Equivalence. In Part II of this Appendix we discuss the intertemporal model in greater detail. Expanding the production function in a Taylor series around the general equilibrium up to the second-order terms yield

$$(A5) \quad \Delta Y = \bar{Y}_L\Delta L - \frac{1}{2}\bar{Y}_{LL}(\Delta L)^2.$$

where  $\Delta Y = \bar{Y}(\tilde{L}) - Y(L)$ . Since the expansion is around the equilibrium, we substitute in (A5) the equilibrium real wage for  $\bar{Y}_L$ , and then substitute the resulting expression for  $\Delta C (= \Delta Y)$  into (A4):

$$(A6) \quad \Delta U/\lambda = -\frac{1}{2}\bar{Y}_{LL}(\Delta L)^2 + \frac{1}{2}\Delta(\bar{W}/P)^s\Delta L,$$

or, equivalently,

$$(A6') \quad \Delta U/\lambda = \frac{1}{2}(-\bar{Y}_{LL} + \epsilon')(\Delta L)^2,$$

where  $\epsilon'$  denotes the slope of the supply of labor, that is,  $\epsilon' \equiv \Delta(\bar{W}/P)^s/\Delta L$ . Multiplying and dividing the right hand side of (A6') by  $\tilde{L}^2$  yields

$$(A6'') \quad \Delta U/\lambda = (\tilde{L}^2/2)[- \bar{Y}_{LL} + \epsilon'](\tilde{l} - l)^2,$$

where  $\tilde{l} - l$ , which is defined as  $\log(\tilde{L}/L_0) - \log(L/L_0)$ , approximates the percentage discrepancy between equilibrium and actual employment levels (where we employ the approximation that  $\log(1+x) \approx x$ ). Using the production function to compute  $\bar{Y}_{LL}$ , we obtain

$$(A7) \quad \Delta U/\lambda = \left(\frac{1}{\epsilon} + \frac{1}{\sigma}\right)\frac{\tilde{L}}{2}\left(\frac{\tilde{W}}{P}\right)(l - \tilde{l})^2,$$

where  $\epsilon$  denotes the elasticity of labor supply and, as defined in the text,  $\sigma = 1/(1-\beta)$  where  $\beta$  denotes the elasticity of output with respect to labor input. Substituting for  $(l - \tilde{l})^2$  from equation (27) in the text yields

$$(A8) \quad \frac{\Delta U}{\lambda} = \frac{\sigma^2}{2}\left(\frac{1}{\epsilon} + \frac{1}{\sigma}\right) \times \left[-(w - p) + \frac{\sigma E(\mu)}{\sigma + \epsilon}\right]^2 \left(\frac{\tilde{W}}{P}\right)\tilde{L},$$

where (A8) corresponds to equation (30) in the text. Our loss function is defined as the expected value of the welfare loss from sub-optimal employment during period  $t$  resulting from the existence of contracts that were agreed upon on the basis of information available at period  $t-1$ . Thus, ignoring the constant  $(\sigma^2/2)(1/\epsilon + 1/\sigma)$  and treating the equilibrium wage bill,  $(\bar{W}/P)\tilde{L}$ , as constant (i.e., ignoring third-order terms of Taylor expansion) we obtain the loss function  $H$ :

$$(A9) \quad H = E\left[\left\{-(w - p) + \frac{\sigma}{\sigma + \epsilon}E(\mu)\right\}^2 | I_{t-1}\right],$$

which corresponds to equation (31) in the text.

*Part II:* Here we demonstrate that the same objective function also applies to a dynamic

intertemporal model. Consider a two-period model and let the present value of utility  $U$  be

$$(A10) \quad U = u(C_1, L_1) + \bar{p}u(C_2, L_2),$$

where  $\bar{p}$  designates the subjective discount factor and where the subscripts 1 and 2 designate variables pertaining to periods 1 and 2, respectively. The value of assets which are not consumed in period 1 is  $A_1$  and their value in period 2 is  $(1+r)A_1$  where  $r$  designates the exogenously given (stochastic) world rate of interest on internationally traded bonds. Denoting rents by  $R$  and assuming that these are redistributed as lump sum transfers, the periodic transfers are the value of output minus the wage bill:

$$(A11) \quad R_t = Y_t(L_t) - \left(\frac{W}{P}\right)_t L_t, \quad (t=1,2).$$

The formal maximization problem in period 2 can be written as

$$(A12) \quad \max E_2[u(C_2, L_2)]$$

subject to

$$C_2 = (1+r)A_1 + \left(\frac{W}{P}\right)_2 L_2 + R_2.$$

The solution to the maximization problem in (A12) yields the optimal values of consumption and labor supply in that period,  $C_2^*$  and  $L_2^*$ . These optimal values are conditional, of course, on the historically given value of  $A_1$ . Thus, we can define a function  $u^*(A_1)$  where  $u^*(A_1) \equiv u(C_2^*, L_2^*)$ . We then can present the maximization problem for period 1 as

$$(A13) \quad \max E_1[u(C_1, L_1) + \bar{p}u^*(A_1)],$$

$$\text{subject to } C_1 = Q + \left(\frac{W}{P}\right)_1 L_1 + R_1 - A_1,$$

where  $Q$  denotes the given initial endowment. The solution to (A13) yields the optimal values  $\bar{C}_1$ ,  $\bar{L}_1$ , and  $\bar{A}_1$ . As before we denote the value of utility in the general equilibrium by  $U(\bar{L}_1)$  where it is understood

that this level of utility is obtained when  $C_1$ ,  $L_1$ , and  $A_1$  are set at their unconstrained optimal values  $\bar{C}_1$ ,  $\bar{L}_1$ , and  $\bar{A}_1$ . In practice, due to contracts, the level of employment may be constrained to  $L_1$ . The resulting level of utility would be  $U(L_1)$ , where it is understood that  $C_1$  and  $A_1$  are still chosen optimally subject to the constraint that the labor supply is  $L_1$ . The welfare cost would be  $[U(\bar{L}_1) - U(L_1)]/\lambda$ .

In computing the welfare cost we apply Harberger's formula (A3) where we note that in the present case one of the arguments in the underlying utility function is the asset position  $A_1$ . Thus the expression corresponding to (A4) becomes

$$(A14) \quad \Delta U/\lambda \approx \Delta C_1 - (\bar{W}/\bar{P})_1 \Delta L_1 + \Delta A_1 + \frac{1}{2} \Delta (W/P)_1^s \Delta L_1.$$

Using the constraint in (A13) we obtain

$$(A15) \quad \Delta C_1 + \Delta A_1 = \Delta \left[ \left(\frac{W}{P}\right)_1 L_1 + R_1 \right],$$

and using the definition of  $R_1$  from (A11) the expression in (A15) equals the change in output  $\Delta Y_1$ , which is substituted in (A14) to yield

$$(A16) \quad \Delta U/\lambda \approx \Delta Y_1 - (\bar{W}/\bar{P})_1 \Delta L_1 + \frac{1}{2} \Delta (W/P)_1^s \Delta L_1.$$

Finally, by using (A5) for  $\Delta Y_1$  we can proceed along identical lines to those in Part I of this Appendix so as to yield the objective function used in the text.

We have thus demonstrated that the dynamic problem could be transformed into the simpler static counterpart used in Part I of the Appendix. The assumption necessary for this transformation is that the utility function is separable. To ensure that the resultant objective function remains invariant with respect to monetary policy, it is also assumed that the private sector fully internalizes the central bank's asset position.

Prior to concluding this Appendix we can now use the loss function in order to justify

our earlier assumption concerning the initial nominal wage,  $W_0$ . Using the definition of the variance, the loss function (A9) can be written as

$$(A9') \quad H = \text{Var} \left[ -(w-p) + \frac{\sigma}{\sigma + \varepsilon} E(\mu) | I_{t-1} \right] \\ + E \left[ \left\{ -(w-p) + \frac{\sigma}{\sigma + \varepsilon} E(\mu) \right\} | I_{t-1} \right]^2.$$

Our assumption that the initial contractual nominal wage is set at the level that would have prevailed in equilibrium in the absence of shocks, is necessary in order to ensure that the second term on the right-hand side of (A9') vanishes; for any other choice of  $W_0$  this second term would be positive (since  $E[-(w-p) | I_{t-1}]$  would not be zero), and the welfare loss would not be minimized.

# Network Externalities, Competition, and Compatibility

By MICHAEL L. KATZ AND CARL SHAPIRO\*

There are many products for which the utility that a user derives from consumption of the good increases with the number of other agents consuming the good. There are several possible sources of these positive consumption externalities.<sup>1</sup>

1) The consumption externalities may be generated through a direct physical effect of the number of purchasers on the quality of the product. The utility that a consumer derives from purchasing a telephone, for example, clearly depends on the number of other households or businesses that have joined the telephone network. These network externalities are present for other communications technologies as well, including Telex, data networks, and over-the-phone facsimile equipment.

2) There may be indirect effects that give rise to consumption externalities. For example, an agent purchasing a personal computer will be concerned with the number of other agents purchasing similar hardware because the amount and variety of software that will be supplied for use with a given computer will be an increasing function of the number of hardware units that have been sold. This hardware-software paradigm also applies to video games, video players and recorders, and phonograph equipment.

3) Positive consumption externalities arise for a durable good when the quality and availability of postpurchase service for the good depend on the experience and size of the service network, which may in turn vary with the number of units of the good that have been sold. In the automobile market, for example, foreign manufacturers' sales initially were retarded by consumers' awareness of the less experienced and thinner service networks that existed for new or less popular brands.

In all of these cases, the utility that a given user derives from the good depends upon the number of other users who are in the same "network" as is he or she. The scope of the network that gives rise to the consumption externalities will vary across markets. In some cases, such as the automobile example, the sales of only one firm will constitute the relevant network. In other cases, the relevant network will comprise the outputs of all firms producing the good. For example, the number of stereo phonographs of any one brand is not a determinant of the supply of records that a consumer can play on his or her stereo. In still other markets, the network may comprise the products of a coalition of firms that is a subset of the entire market, as in the case of computers, where some groups of manufacturers adopt common operating systems.

The central feature of the market that determines the scope of the relevant network is whether the products of different firms may be used together. For communications networks, the question is one of whether consumers using one firm's facilities can contact consumers who subscribe to the services of other firms. If two firms' systems are interlinked, or compatible, then the aggregate number of subscribers to the two systems constitutes the appropriate network. If the systems are incompatible, such as Telex and cable, then the size of an individual

We also thank seminar participants at Princeton, Columbia, Queens, the Federal Trade Commission, and MIT for comments. This material is based upon work supported by the National Science Foundation under grants nos. SES-820942 and SES-82-07377.

<sup>1</sup>In addition to the sources of consumption externalities mentioned in this paper, there are a number of more subtle ones. These include: (i) the fact that product information is more easily available for more popular brands; (ii) the role of market share as a signal of product quality; and (iii) purely psychological, bandwagon effects.

system is the proper network measure for users of that system.

Similarly, for hardware-software markets, the issue is whether software produced for use on one brand of hardware may be run on another brand of hardware. If two brands of hardware can use the same software, then the hardware brands are said to be compatible. The relevant network is the set of users who have compatible brands of hardware. In the personal computer market, the CPM operating system has been designed to allow several brands of computers to use common programs. In the case of quadraphonic audio discs, on the other hand, the records made for one type of player cannot be used on a player that uses a different quadraphonic technology. Here, unlike the case of stereos, the relevant network for a given brand of equipment comprises the set of brands that use the same technology, not the entire market.

For the durables example, the relevant network is the set of brands that require the same parts of servicing skills. If a particular model of automobile has customized parts or requires specialized repair skills, then an owner of the model will find a thinner, and probably more expensive, service system. This smaller network will reduce his or her initial willingness to pay for the model.

Despite the significance of markets in which network externalities are present, relatively little work has been done in this area. The analysis done so far has been set in a monopoly context and has focussed on communications networks. Shmuel Oren and Stephen Smith (1981) is a recent reference to this literature. As the examples above make clear, it is important to extend the study of network externalities to an oligopolistic setting.

In this paper, we develop a simple, static model of oligopoly to analyze markets in which consumption externalities are present. We examine two basic sets of issues. First, we study the effect of consumption externalities on competition and the form of the market equilibrium. When network externalities exist, consumers must form expectations regarding the size of competing networks.

We use a notion of rational, or fulfilled expectations, equilibrium. Our basic findings are that consumption externalities give rise to demand-side economies of scale, which will vary with consumer expectations. As a result, multiple fulfilled expectations equilibria may exist for a given set of cost and utility functions. For some sets of expectations only one firm will produce output, while for other sets of expectations there will be several firms in the market. These equilibria verify the following intuition: if consumers expect a seller to be dominant, then consumers will be willing to pay more for the firm's product, and it will, in fact, be dominant.

The second area that we explore is the compatibility decision. Typically, firms can choose whether to manufacture compatible products, and thus can determine whether individual firm or aggregate market sales are the relevant ones in the evaluation of the consumption externalities. An important question, therefore, is whether firms will have proper incentives to produce compatible goods or services.

Gerald Brock (1975) and Robert Kurdle (1975) have done interesting case studies of compatibility decisions in the U.S. mainframe computer and farm machinery industries, respectively. Neither, however, develops a model of equilibrium in which to analyze firms' compatibility incentives. Using our model, we compare the private and social incentives to produce compatible products. We find that firms with good reputations or large existing networks will tend to be against compatibility, even when welfare is increased by the move to compatibility. In contrast, firms with small networks or weak reputations will tend to favor product compatibility, even in some cases where the social costs of compatibility outweigh the benefits. Viewing firms as a collective decision maker, we find that in our model the firms' joint incentives for product compatibility are lower than the social incentives.

The paper is organized as follows. In Section I, we present the model and define the equilibrium concept. The set of market equilibria is characterized in Section II. We ex-

amine the private and social incentives for compatibility in Section III, primarily under the assumptions that all of the costs of compatibility are fixed. There is a brief summary of our results and a discussion of the relevance of these results for public policy in Section IV. We outline an alternative approach to the formation of consumer expectations in the Appendix. It is shown that the equilibria are qualitatively similar if the firms are able to commit to given network sizes before consumers make their purchase decisions.

## I. A Formal Model of Network Competition

### A. Consumers

We look at a partial equilibrium oligopoly model in which there are no income effects and consumers act to maximize their surplus. A consumer buys at most one brand and purchases either one or no unit of any given brand.

The surplus that a consumer derives from buying a unit of the good depends on the number of other agents who join the network associated with that product. When the good is durable, an individual's consumption benefits will depend on the future size of the relevant network. Consumers will base their purchase decisions on *expected* network sizes. To capture this important feature of many markets with network externalities in our static, one-period model, we assume that consumers must make their purchase decisions before the actual network sizes are known. The timing is as follows. First, consumers form expectations about the size of the network with which each firm is associated. Second, the firms play an output game, taking consumers expectations as given. This game generates a set of prices. Consumers then make their purchase decisions by comparing their reservation prices (based on expected network sizes) with the prices set by the  $n$  firms,  $i = 1, \dots, n$ .

We do not explicitly model the process through which consumers' expectations are formed. We will, however, impose the requirement that in equilibrium consumers' expectations are fulfilled. Let  $x_i^e$  denote the

number of customers that a consumer expects firm  $i$  to have, and let  $y_i^e$  be the consumer's prediction of the size of the network with which firm  $i$  is associated. All consumers are assumed to have identical expectations of network sizes. When the brands are incompatible, each makes up its own network so  $y_i^e = x_i^e$ . When  $m$  firms' products are compatible, say brands 1 through  $m$ , then there is a single network for these brands and

$$y_i^e = \sum_{j=1}^m x_j^e \quad \text{for } i = 1, 2, \dots, m.$$

Networks are assumed to be homogeneous in the sense that if two networks are of equal size, then all consumers view the two networks as perfect substitutes.

Consumers are assumed to be heterogeneous in their basic willingness to pay for the product, but homogeneous in their valuations of the network externality. Specifically, a consumer of type  $r$  has a willingness to pay  $r + v(y^e)$  for a product with expected network size  $y^e$ . Without further loss of generality we can normalize  $r$  and  $v(0)$  so that  $v(0) = 0$ . We can interpret  $r$  as the consumer's basic willingness to pay for the good and  $v(y)$  as the value he or she attaches to the consumption externality when the number of subscribers is  $y$ . The externality function is taken to be twice continuously differentiable, with  $v' > 0$ ,  $v'' < 0$ , and  $\lim_{y \rightarrow \infty} v'(y) = 0$ . The basic willingness to pay for the good,  $r$ , varies across consumers and is assumed to be uniformly distributed between minus infinity and  $A$  with density one.<sup>2</sup> We assume that  $A$  is positive.

Each agent purchases the brand that maximizes his or her surplus. Letting  $p_i$  denote the price charged for brand  $i$ , a consumer of type  $r$  chooses the brand for which

$$(1) \quad r + v(y_i^e) - p_i$$

<sup>2</sup> The uniform density assumption amounts to assuming a linear demand curve for the product. We assume that the support of  $r$  has no finite lower limit in order to avoid having to consider corner solutions, where all consumers enter the market.

is largest. If (1) is negative for all  $i$ , then a type  $r$  consumer stays out of the market and purchases none of the brands.

### B. Firms

Given the homogeneity of the products, two firms  $i$  and  $j$  will both have positive sales only if

$$(2) \quad p_i - v(y_i^e) = p_j - v(y_j^e),$$

where  $p_i - v(y_i^e)$  is the expected hedonic price of brand  $i$ , that is, the price adjusted for the network size. Equation (2) says that the hedonic prices must be equal when multiple firms have positive sales. Let  $\phi$  denote the common value of the hedonic prices given in equation (2).

For a given value of  $\phi$ , only those consumers for whom  $r \geq \phi$  enter the market. Given the uniform distribution of  $r$ , there are  $A - \phi$  such consumers. Thus, if the firms sell a total of  $z \equiv \sum_{i=1}^n x_i$  units, then prices must be set such that  $A - \phi = z$ , or

$$(3) \quad A + v(y_i^e) - p_i = z$$

for all  $i$  such that  $x_i > 0$ .

From equation (3) we see that firm  $i$  receives a price of

$$(4) \quad p_i = A + v(y_i^e) - z.$$

The price that firm  $i$  receives depends on the expected size of its network,  $y_i^e$ , and on the total unit sales of the  $n$  firms,  $z$ .

There are two types of costs that must be modeled. First, there are costs of production. We assume that production costs are the same for all firms and that these costs take the form of a fixed cost,  $G$ , plus a constant per unit variable cost,  $g$ . That is, the cost to firm  $i$  of producing  $x$  units of output is  $G + gx$ . As long as the fixed costs are smaller than the firm's equilibrium revenues minus variable costs, the fixed costs have no effect on the equilibrium. To simplify the exposition, we assume that the fixed costs of production are equal to zero. Without loss of generality, we also take the variable costs of

production to be equal to zero. Assuming that  $g$  is equal to zero is equivalent to redefining  $r$  to be the excess of the consumer's basic willingness to pay for the good over the constant per unit cost.<sup>3</sup>

There is a second type of cost that we must consider, the cost of the achieving compatibility. For most of the analysis we will assume that the costs of compatibility are fixed costs, that is, are independent of scale. This amounts to assuming that compatible products have the same marginal production costs as incompatible products. (We discuss the consequences of relaxing this assumption of Section III, Part D). The fixed cost of compatibility that we analyze could include costs of developing and designing a compatible product, the costs of negotiating to select a standard, and the costs of introducing a new, compatible product. Let  $F_i$  denote the fixed costs of compatibility incurred by firm  $i$ . Note that  $F_i$  need not be the same for all firms.

If all of the networks are incompatible, then  $y_i^e = x_i^e$ , and firm  $i$  earns profits equal to

$$(5) \quad \pi_i = x_i(A - z + v(x_i^e))$$

when it has sales of  $x_i$  and total output is  $z$ .

When all  $n$  products are compatible,  $y_i^e = \sum_{j=1}^n x_j^e \equiv z^e$ , for all  $i$ . Therefore, when total output is  $z$  and firm  $i$  has sales of  $x_i$ , the firm's gross profits are

$$(6) \quad \pi_i = x_i(A - z + v(z^e)),$$

from which we must subtract  $F_i$  to get profits net of the fixed costs of compatibility.

### C. Fulfilled Expectations Equilibrium

Our equilibrium concept is that of fulfilled expectations Cournot equilibrium, where each firm chooses its output level under the assumptions that: (a) consumers' expecta-

<sup>3</sup>It is for this reason that negative values of  $r$  make sense; the redefined variable  $r$  measures the excess of a consumer's basic willingness to pay over the marginal production costs of an additional unit.

tions about the sizes of the networks,  $(y_1^e, y_2^e, \dots, y_n^e)$ , are given; and (b) the actual output level of the other firms,  $\sum_{j \neq i} x_j \equiv x_{-i}$ , is fixed.

Assumption (b) is the standard Cournot assumption. For any fixed set of consumer expectations, the problem is equivalent to the standard linear demand Cournot model with constant marginal costs. Assumption (a) is relaxed in the Appendix, which considers the case in which the  $y_i^e$ s are formed *after* the firms have selected their output levels. Differentiating equation (5) and rearranging terms, the first-order conditions  $d\pi_i/dx_i = 0$  imply that the equilibrium sales levels  $(x_1^*, x_2^*, \dots, x_n^*)$  must satisfy

$$(7) \quad x_i^* = A + v(y_i^e) - \sum_{j=1}^n x_j^* \quad \text{for } i=1, 2, \dots, n.$$

Note that the right-hand side of equation (7) equals  $p_i$ .

For any given set of expectations, we can solve equation (7) simultaneously for the  $x_i^*$ s to obtain the unique Cournot equilibrium that corresponds to that set of expectations:

$$(8) \quad x_i^* = \left\{ A + nv(y_i^e) - \sum_{j \neq i} v(y_j^e) \right\} / (n+1) \quad \text{for } i=1, 2, \dots, n.$$

The outcome is just the standard linear demand Cournot equilibrium where the differences in  $v(y_i^e)$  are analogous to production cost differences. Equation (8) defines a function that maps expectations  $(y_1^e, y_2^e, \dots, y_n^e)$  into Cournot equilibrium network sizes  $(y_1^*, y_2^*, \dots, y_n^*)$  for a given pattern of compatibility. Let  $\Gamma(y^e)$  denote this function.

In the absence of rationality constraints on consumer expectations, there is a Cournot equilibrium for any set of expectations. But for most sets of expectations, the expectations will not be fulfilled in the corresponding Cournot equilibrium; the actual network

sizes are not equal to the expected ones. Although it is possible that (in the short run, at least) consumers could be mistaken about network sizes, it is useful to limit the set of possible equilibria by imposing the restriction that expected sales be equal to actual sales in equilibrium. Formally, our equilibrium notion is that of Fulfilled Expectations Cournot Equilibrium (*FECE*), where a *FECE* is an  $n$ -vector of network sizes  $y^* = (y_1^*, y_2^*, \dots, y_n^*)$ , such that  $y^* = \Gamma(y^*)$ . If consumers expect the network sizes to be  $y^*$ , then in the corresponding Cournot equilibrium the network sizes will indeed equal  $y^*$ ; consumers' expectations will be fulfilled.

#### D. Welfare Formulae

Given the cost and demand assumptions that we have made, profits and welfare can be written as functions of the firms' individual levels of output. By equation (7), in equilibrium, firm  $i$ 's output level is equal to the price that firm receives. Thus, the  $i$ th firm's profits in equilibrium are  $\pi_i = (x_i^*)^2$ . We will denote aggregate profits by  $\pi \equiv \pi_1 + \dots + \pi_n$ .

The surplus that a consumer derives from joining a network depends on the *actual* size of the network; in equilibrium, the actual size will equal that network's *expected* size. By equations (1) and (3), when market output is  $z$ , a type  $r$  consumer expects to derive surplus of  $r + z - A$  from joining a network. Only those consumers for whom  $r$  is greater than  $A - z$  join a network; the other consumers stay out of the market and derive no surplus. Integrating over all consumers who do enter the market, we obtain consumers' expected surplus

$$(9) \quad S(z) = \int_{A-z}^A (p + z - A) dp = z^2/2.$$

In any fulfilled expectations equilibrium, expected and actual consumers' surplus will be equal, and we can use equation (9) when discussing actual consumers' surplus.

We take the sum of producers' and consumers' surplus as our social welfare measure. Hence, in any fulfilled expectations

Cournot equilibrium, welfare (gross of the fixed costs of compatibility) is given by

$$(10) \quad W(x_1, \dots, x_n) = \pi(x_1, \dots, x_n) + S(x_1 + \dots + x_n) = \sum_{i=1}^n x_i^2 + z^2/2.$$

## II. The Characterization of Equilibria

In this section, we examine the structure of fulfilled expectations equilibria for compatible and incompatible products, respectively.

### A. Complete Compatibility

Suppose that any two products are compatible with one another. Then there is a single network of expected size  $z^e = \sum_{i=1}^n x_i^e$ , and for all  $i$ ,  $y_i^e = z^e$ . Equation (8) becomes

$$(11) \quad x_i^* = (A + v(z^e))/(n+1) \quad \text{for } i=1, 2, \dots, n.$$

If we impose the fulfilled expectations requirement that  $z^e = x_1^* + \dots + x_n^*$  and sum equation (11) over all  $i$ , we obtain

$$(12) \quad z^c = (n/(n+1))(A + v(z^c)),$$

where  $z^c$  denotes the fulfilled expectations equilibrium value of total output when the products are compatible. Under our assumptions on  $v(\cdot)$ , equation (12) has a unique solution, as is clear from Figure 1. This unique compatible-products equilibrium is symmetric:  $x_i^c = z_i^c/n$  for all  $i$ . We have shown:

**PROPOSITION 1:** *When all products are mutually compatible, there is a unique FECE. It is symmetric, and the aggregate level of output is given implicitly by equation (12).*

As the number of firms becomes increasingly large, the compatibility equilibrium converges to the perfectly competitive equilibrium;  $z^c$  approaches  $A + v(z^c)$ , and the hedonic price,  $A + v(z^c) - z^c$ , approaches the marginal cost level of zero.

FIGURE 1. EQUILIBRIUM WITH COMPLETE COMPATIBILITY

### B. Complete Incompatibility

Now we consider the case where any two brands are incompatible with one another so that  $y_i^e = x_i^e$ . In equilibrium, each firm  $i$  is optimizing given the actions of the other firms,  $x_j$ ,  $j \neq i$ , and consumers' expectations,  $x_i^e$ . Using equation (7) in conjunction with the fulfilled expectations condition  $x_i = x_i^e$ , we have  $x_i = A + v(x_i) - z$ , or

$$(13) \quad \sum_{j \neq i} x_j = A + v(x_i) - 2x_i \quad \text{for } i=1, 2, \dots, n.$$

For a given value of  $x_{-i}$ , equation (13) can be solved for  $x_i$ . The graph of equation (13) is called firm  $i$ 's *equilibrium reaction correspondence*. One possible shape of this correspondence is illustrated in Figure 2.<sup>4</sup>

The equilibrium reaction correspondence should not be confused with a standard reaction function. The latter merely states firm  $i$ 's best response to the other firms, given consumer expectations. There will be a different reaction function for each set of expectations. The equilibrium reaction corre-

<sup>4</sup>It is also possible that firm  $i$ 's reaction schedule is strictly downward sloping. This will occur if and only if  $v'(0) < 2$ .

FIGURE 2. FIRM  $i$ 'S EQUILIBRIUM REACTION CORRESPONDENCE

spondence gives the set of points such that if the other firms played  $x_{-i}$  and consumers expected brand  $i$  to have a network size of  $x_i$ , then  $x_i$  would in fact be firm  $i$ 's best response. Suppose the other firms set their output at  $\hat{x}_{-i}$  in Figure 2. Then firm  $i$ 's best response to  $\hat{x}_{-i}$  would fulfill consumer expectations if these expectations were either  $\tilde{x}_i$  or  $\bar{x}_i$ . Note that firm  $i$  treats consumer expectations as exogenous, and thus the firm does not choose between  $\tilde{x}_i$  and  $\bar{x}_i$ .

In Figure 2, firm  $i$ 's equilibrium reaction correspondence is drawn to include the  $x_{-i}$  axis for  $x_{-i} > A$ . This part of firm  $i$ 's reaction schedule is not derived from equation (13), which only applies when  $x_i > 0$ . Instead it is derived from the corner condition,  $d\pi_i/dx_i < 0$  at  $x_i = 0$ . When  $x_i^e = x_i = 0$ ,  $d\pi_i/dx_i = A - x_{-i}$ , so it is optimal for firm  $i$  to set  $x_i = 0$  if  $x_{-i}^e = 0$  and  $x_{-i} > A$ .

Having derived the firms' fulfilled expectations reaction schedules, we turn now to the characterization of equilibria. There are three types of equilibria that are possible when the networks of competing firms are incompatible: (i) symmetric oligopoly with  $n$  active firms; (ii) symmetric oligopoly with  $k < n$  active firms, which we call natural oligopoly; and (iii) asymmetric oligopoly.

#### 1. Symmetric Oligopoly.

**PROPOSITION 2:** When each brand is incompatible with all  $(n-1)$  of the other brands,

FIGURE 3. UNIQUE SYMMETRIC EQUILIBRIUM WITH COMPLETE INCOMPATIBILITY

there exists a unique symmetric equilibrium in which  $x_i = z^I/n$  and aggregate sales,  $z^I$ , are given implicitly by

$$(14) \quad ((n+1)/n)z^I = A + v(z^I/n).$$

#### PROOF:

Taking  $x_i = z/n$  and adding up equation (13) for  $i=1, \dots, n$ , gives  $(n-1)z = nA + nv(z/n) - 2z$ . Rearranging yields equation (14), which has a unique solution, as Figure 3 illustrates.

2. *Natural Oligopoly (Not all Firms Active).* While a unique symmetric equilibrium always exists, there are asymmetric equilibria that exist for certain parameter values. Given the symmetry in the equilibrium response correspondences, such asymmetric equilibria always come in sets (where the elements of the set differ from each other only by the transposition of the firms' indices). One such type of equilibrium entails some firms exiting the market (i.e., producing no output) and the other firms behaving as oligopolists with a diminished number of competitors.

**PROPOSITION 3:** A symmetric equilibrium with  $k$  active firms exists if and only if  $v(A/k) \geq A/k$ .

FIGURE 4. NATURAL OLIGOPOLY

## PROOF:

Suppose that  $k$  firms each produce  $x_i = z/k$  units of output, and the remaining  $n - k$  firms produce no output. Adding up equation (13) for the  $k$  active firms, we obtain  $(k - 1)z = kA + kv(z/k) - 2z$ , or

$$(15) \quad ((k + 1)/k)z = A + v(z/k).$$

As Figure 4 illustrates, there will be a unique solution to equation (15). Let  $z^k$  denote this solution.

We must check that the remaining  $n - k$  firms do not have incentives to produce positive output, that is, that  $A + v(0) - z^k = A - z^k < 0$ . Again from Figure 4, it is clear that  $z^k \geq A$  iff  $A + v(A/k) \geq ((k + 1)/k)A$ , or  $v(A/k) \geq A/k$ .

**COROLLARY 3.1:** *For any  $k \leq n - 1$ , if a  $k$ -active-firm symmetric equilibrium exists, then a  $(k + 1)$ -active-firm symmetric equilibrium exists.*

**COROLLARY 3.2:** *For any  $k \leq n - 1$ , if a  $k$ -active-firm symmetric equilibrium exists, then  $z^k < z^{k+1}$ .*

Both corollaries follow from the concavity of  $v(\cdot)$ . Note that equilibrium with  $k = 1$  (the monopoly outcome) or some other low value of  $k$  is more likely to obtain when consumers' basic willingness to pay for the good is low (so that  $A$  is low) or when the

FIGURE 5. NATURAL MONOPOLY EQUILIBRIA

network effects are strong (so that  $v(A)$  is large for a given  $A$ ).

Proposition 3 shows that the network externalities are similar to fixed costs in that they can lead to a limited number of active producers. The analogy between fixed costs and network externalities is not complete, however. This point is demonstrated by Corollary 3.1 and the fact that for the given set of demand conditions, an  $n$ -active-firm equilibrium exists for arbitrarily large  $n$ . In the case of fixed costs, one cannot squeeze an arbitrarily large number of active producers into the industry.

Figure 5 shows the reaction curves for a case in which a natural monopoly equilibrium exists. It is interesting to note that the monopolist's profits, may be *lower* than the profits of a duopolist in the 2-active-firms symmetric equilibrium. In other words, a monopoly may benefit from entry. This unusual result follows from the fulfilled expectations condition: a monopolist will exploit his position with high prices and consumers know this. Thus, consumers expect a smaller network and are willing to pay less for the good. If the monopolist could commit himself to higher sales he would be better off, but this commitment is not credible so long as he is the sole producer.<sup>5</sup>

**3. Asymmetric Oligopoly.** The third possible equilibrium configuration is one in which

<sup>5</sup>We consider the case where commitment is feasible in the Appendix.

FIGURE 6. ASYMMETRIC DUOPOLY

$k \geq 2$  firms produce positive but unequal levels of output. We have constructed examples of such equilibria, although they are difficult to characterize in general. These asymmetric equilibria verify the intuition that a firm may be successful and enjoy a large market share simply because it is expected to by consumers.

One example of an asymmetric duopoly equilibrium is shown qualitatively in Figure 6. Despite a linear demand curve and a concave network valuation function  $v(y)$ , a variety of possibilities may arise. Figure 6 shows a situation in which asymmetric equilibria exist as well as symmetric and natural monopoly equilibria. In other cases, the only stable equilibria are asymmetric ones.

### C. Partial Compatibility

When there are more than two firms, the extent of product compatibility may fall in between complete incompatibility and industrywide compatibility. Assuming that the compatibility relation is symmetric and transitive, the pattern of compatibility can be characterized by the set of compatibility groups,  $G^j$   $j=1, \dots, J$ , where all of the brands within a given group are mutually compatible with each other and are incompatible with any nonmember brands.<sup>6</sup> Thus,

<sup>6</sup>The  $G^j$ ,  $j=1, \dots, J$ , form a partition of the set  $\{1, 2, \dots, n\}$ .

if firm  $i$  is in group  $G^j$ ,

$$y_i = \sum_{k \in G^j} x_k \equiv y^j.$$

For a firm  $i$  in group  $j$ , the first-order condition is  $x_i = A - z + v(y^j)$ . Thus, all firms in a given group will choose the same level of output,  $x^j$ . Let  $m^j$  denote the number of firms in compatibility group  $j$ . Then, in equilibrium, for all  $x^j > 0$  we must have

$$(16) \quad x^j = A - z + v(m^j x^j).$$

Equation (16) has the same qualitative properties as our earlier equilibrium conditions, and similar types of equilibria will arise. Here, we will not characterize these equilibria directly. In the next subsection, however, we will compare the equilibria that obtain under different degrees of compatibility.

### D. The Output Effects of Compatibility Changes

In analyzing compatibility, it is important to understand the effects of an increase in compatibility on the equilibrium levels of output. What happens to output levels if two compatibility groups "merge" to form a new group where all of the brands in the post-merger group are compatible with one another?

**PROPOSITION 4:** *The level of total output is greater under industrywide compatibility than in any equilibrium with less than complete compatibility.*

#### PROOF:

For all firms with positive levels of output,  $x_i = A + v(y_i) - z$ . Adding up over all firms and rearranging gives us  $(n+1)z = nA + \sum v(y_i)$ , as illustrated in Figure 7. Under complete compatibility,  $y_i = z$  for all firms. Absent complete compatibility,  $y_i < z$  for at least one firm. Thus, the curve  $nA + nv(z)$  lies above  $nA + \sum v(y_i)$  where the  $y_i$ 's are

FIGURE 7. COMPLETE VS. INCOMPLETE COMPATIBILITY

determined under incomplete compatibility. Referring to Figure 7, we see that the equilibrium level of  $z$  is greater under industry-wide compatibility.

When the move to increased compatibility does not result in *complete* compatibility, total output need not rise. The following proposition, however, states a sufficient condition for industry output to increase.

**PROPOSITION 5:** *Suppose that two groups of firms make their products mutually compatible. If premerger total output is less than  $A$ , then in any postmerger equilibrium: (a) the average output of the firms in the merging coalitions will rise; (b) the output of any firm not in the merging coalitions will fall; and (c) industry output will rise.*

**PROOF:**

Let  $\hat{x}^j$  denote the premerger output level of a firm in coalition  $j$  and  $\hat{z}$  denote premerger total output. By equation (16),  $\hat{x}^j = A - \hat{z} + v(m^j \hat{x}^j)$ . Figure 8 illustrates this condition, where we have made use of the fact that industry output is less than  $A$ .

Label the compatibility groups that merge as 1 and 2. Let  $\tilde{x}^j$  and  $\tilde{z}$  denote the postmerger output levels analogous to the  $\hat{x}^j$  and  $\hat{z}$ . If total output falls, then for  $j \geq 3$ ,  $A - \tilde{z} + v(m^j \tilde{x}^j)$  will lie everywhere above  $A - \hat{z} + v(m^j \hat{x}^j)$ , and from Figure 8 we see that  $x^j$  will increase (i.e.,  $\tilde{x}^j > \hat{x}^j$ ). By similar argu-

FIGURE 8. EQUILIBRIUM OUTPUT OF A FIRM IN COALITION  $j$

ments,  $\tilde{z} = \hat{z}$  implies  $\tilde{x}^j = \hat{x}^j$  for  $j \geq 3$  and  $\tilde{z} > \hat{z}$  implies  $\tilde{x}^j < \hat{x}^j$  for  $j \geq 3$ .

Now, consider the firms in the merged coalitions. For these firms (i.e.,  $j=1,2$ ),  $A - z + v(m^j x^j) < A - \tilde{z} + v(m^1 \tilde{x}^1 + m^2 \tilde{x}^2)$  as long as  $x^1$  and  $x^2$  are positive. The effect of compatibility is to shift up the  $A - z + v$  curve when viewed as a function of  $x^j$  (as in Figure 8). The effect of  $z$  on this curve is the same as for  $j \geq 3$ . Therefore if  $\tilde{z} \leq \hat{z}$ , then  $\tilde{x}^j > \hat{x}^j$  for  $j=1,2$ .

Suppose that  $\tilde{z} \leq \hat{z}$ . Then  $\tilde{x}^j \geq \hat{x}^j$  for all  $j$ , with strict inequality for  $j=1,2$ . But  $z = \sum m^j x^j$ , so we have a contradiction. Therefore, industry output rises due to the increased compatibility;  $\tilde{z} > \hat{z}$ . We already have shown that an increase in industry output implies that firms not in the merging coalitions produce less;  $\tilde{z} > \hat{z}$  implies  $\tilde{x}^j < \hat{x}^j$  for  $j \geq 3$ . Thus, it must be the case that the firms in the merging coalitions produce more:  $m^1 \tilde{x}^1 + m^2 \tilde{x}^2 > m^1 \hat{x}^1 + m^2 \hat{x}^2$ .

Note that Proposition 5 does *not* state that the new level of per firm output for the enlarged coalition will be larger than both  $\hat{x}^1$  and  $\hat{x}^2$ ; it states only that the new level of output will be larger than their mean. Note also that by Proposition 4, if total output under complete compatibility,  $z^c$ , is less than  $A$ , then  $z < A$  in *any* equilibrium. From equation (12),  $z^c < A$  if  $v(A) < A/n$ . So,

$v(A) < A/n$  is sufficient for  $\hat{z} < A$ , the hypothesis of Proposition 5.

When industry output in the premerger equilibrium equals or exceeds  $A$ , an increase in compatibility may be accompanied by a reduction in both industry output and the average level of output of the firms in the merging coalitions. To see this point, consider the following example. There are  $n$  firms,  $v(A) \geq A$ , and initially there is complete incompatibility. By Proposition 2, there exists a unique symmetric equilibrium in which all  $n$  firms are active. By Proposition 3, there exist  $n$  natural monopoly equilibria, each of which entails the natural monopolist producing  $A$  or more units of output. The natural monopolist's output level is less than that of the industry in the  $n$ -active-firm symmetric equilibrium (Corollary 3.2).

Suppose that the industry initially is in the  $n$ -active-firm symmetric equilibrium, and that some, but not all, of the firms form a compatibility coalition. The natural monopoly equilibria where a nonmerging firm is the natural monopolist will remain equilibria after the merger. Thus, while the premerger equilibrium entailed all firms active, the postmerger equilibrium could be one in which all but one firm shuts down. As we have just stated, industry output falls in this case. Moreover, the firms who formed the compatibility coalition are among those who were active in the premerger equilibrium, but are inactive in the postmerger equilibrium.

### III. The Private and Social Incentives for Network Compatibility

To this point, we have treated the compatibility of the products as an exogenous characteristic of the market. In most markets where network externalities are important, the compatibility of the products will be the result of explicit decisions by the firms. When the network externalities are large, the choice of whether to make the products compatible will be one of the most important dimensions of market performance.

There are many cases in which firms will disagree on the desirability of making their products compatible; the move to compati-

bility may increase the profits of some firms while lowering the profits of others. Thus, we must be careful to specify the mechanism by which compatibility is achieved and whether side payments among firms are feasible.

It is useful to think of there being two basic technologies by which compatibility can be achieved. First, compatibility may arise through the *joint adoption of a product standard*, where a given set of firms must act together to make their products compatible with one another. The CPM operating system for personal computers and the broadcast television standards are two examples. Second, compatibility can be achieved through the *construction of an adapter*, where a single firm can act unilaterally to make its product compatible with those of another firm or group of firms. In the 1960's, for example, Honeywell developed a program that would allow its mainframe computers to run programs initially written for IBM hardware.<sup>7</sup> At present, there is intense competition, both in the market and in the courts, as the video game manufacturers such as Coleco develop adapters that allow their hardware to run the video game programs of competing firms. In other cases there need not be a physical adapter; one firm can adopt another network's specifications for its product design.

When the firms cannot make side payments among one another and when the compatibility mechanism is a product standard, the products of a given set of firms will be made compatible if and only if *all* of these firms would earn greater profits as a result. In contrast, when the compatibility mechanism is an adapter, and side payments are infeasible, the products of two firms will be made compatible if *either* firm would find the move to be profitable.

When side payments are feasible, the firms will make their products compatible if and only if the change in the profits of firms within the set that can make side payments to one another exceeds the joint costs of compatibility.

<sup>7</sup>See Brock, p. 78.

We will examine several cases that vary in terms of the compatibility technology and feasibility of side payments. In analyzing the private incentives for compatibility, we will look at each firm's change in profits,  $\Delta\pi_i = \pi_i^c - \pi_i^I$ , and the change in their joint profits  $\Delta\pi = \sum_{i=1}^n \Delta\pi_i$ , and we compare these with the costs of compatibility. For most of this section we will take these costs to be purely fixed costs. The social incentives for compatibility are given by  $\Delta W = W^c - W^I$ . We denote the change in consumers' surplus by  $\Delta S = S^c - S^I$ .

#### A. The Incentive when Side Payments among All Firms are Feasible

If side payments among all firms are feasible, then a set of side payments could be constructed so that all firms' profits would be increased individually if and only if compatibility would raise joint profits; the private incentives are given by the change in industrywide profits under either compatibility technology.<sup>8</sup> The change in social welfare,  $\Delta W = \Delta\pi + \Delta S$ ; so the social and private incentives will diverge when the move to compatibility changes the level of consumers' surplus. Since  $S(z) = z^2/2$ , consumers' surplus will go up if and only if output does. By Proposition 4, we know that output and, hence, consumers' surplus will rise with the move to full compatibility. Thus, if  $\Delta\pi > 0$ , then  $\Delta W = \Delta\pi + \Delta S > 0$ .

**PROPOSITION 6:** *When compatibility costs are purely fixed costs, any move to complete compatibility that raises industry profits is socially beneficial.*

Proposition 6 states that firms' incentives for compatibility are not socially excessive. In fact, they may be inadequate. Since  $\Delta S > 0$ ,  $\Delta W > \Delta\pi$ . If the industrywide costs of

compatibility,  $F$ , satisfy  $\Delta\pi < F < \Delta W$ , then the private firms will fail to adopt a socially desirable system of compatibility. The reason is that the firms cannot appropriate all the benefits of compatibility.<sup>9</sup>

**PROPOSITION 7:** *Even when arbitrary side payments among all firms are feasible, profit-maximizing firms may fail to achieve complete compatibility in cases where complete compatibility is socially optimal.*

A similar pair of results can be derived from Proposition 5 for markets in which the initial equilibrium entails  $z < A$  and compatibility is increased (although not necessarily to industrywide compatibility). This result too relies on the fact that the move to increased compatibility raises total output under the stated conditions.

#### B. The Adoption of an Industry Standard

When the compatibility mechanism is the adoption of an industry standard, the firms must jointly decide to make their networks compatible. Any firm can veto the move to compatibility. Therefore, if no side payments are feasible, the standard will be adopted if and only if all firms joining the standard benefit from its creation. If we assume that firm  $i$  bears a cost  $F_i$  to adopt the standard and that side payments are infeasible, then adoption will occur if and only if  $\Delta\pi_i > F_i$  for all adopters of the standard.

Suppose that side payments are feasible only when made among firms achieving compatibility. Such side payments might take the form of licensing fees or compensation for the expenses of making the products compatible, for example. In this case, a sufficient condition for achieving compatibility with a standards technology is that the joint profits of the firms achieving compatibility rise.

<sup>8</sup>Instead of payments made in return for not achieving compatibility, we might see expenditures on legal proceedings aimed at blocking the move to compatibility.

<sup>9</sup>This result is analogous to the fact that a monopolist may be unable to earn a positive profit by providing a socially useful product if there are fixed costs and he or she cannot perfectly price discriminate.

It is clear that, when the compatibility technology is a standard, allowing cost sharing will raise the likelihood of the firms choosing compatibility. If each firm prefers adoption of the standard ( $\Delta\pi_i > F_i$  for all  $i$ ), then the firms in aggregate will ( $\sum \Delta\pi_i > \sum F_i$ ), while the converse is not true. Thus, we can strengthen Proposition 6:

**PROPOSITION 8:** *The private standardization rule is more stringent when cost sharing is infeasible than when it is feasible. The set of cases in which the firms fail to adopt a socially beneficial standard is therefore larger. It remains true that any privately profitable industrywide standard is desirable.*

To see the effect of cost sharing, suppose that there are only two firms in the industry. The compatibility equilibrium is symmetric, so the firm with the smaller incentive to adopt a standard is the one with initially higher profits, that is, the initially larger producer, say firm 1. If the initial equilibrium is symmetric and  $F_1 = F_2 = F$ , then  $\Delta\pi_1 - F = \Delta\pi_2 - F$  and the presence or absence of cost sharing or other side payments is irrelevant. If the initial equilibrium is asymmetric, however, the condition for standardization,  $\Delta\pi_1 > F$  is *strictly* more stringent than the adoption condition with side payments,  $\Delta\pi > 2F$ . The problem is that the larger firm will lose market share to its smaller rival as a result of standardization. If it can unilaterally block standardization, it may do so, despite the fact that its rival and consumers would benefit. Permitting cost sharing and other side payments will help alleviate the problem of insufficient private adoption incentives for moves to complete compatibility.

When the compatibility increase is to less than complete compatibility, private incentives may be excessive, and such cost sharing may exacerbate the problem. There are two reasons why private incentives may be excessive. First, when the increase is to less-than-complete compatibility, total output and consumers' surplus may fall, so that  $\Delta\pi > \Delta W$ . Second, there will be some firms that are not members of the groups making their products compatible. As shown in the proof

of Proposition 5, these firms may produce less output and thus have lower profits in the new equilibrium. Absent side payments from these firms, the firms considering compatibility will not take the losses of other firms ( $\sum_{j \neq i} \Delta\pi_j < 0$ ) into account. The social incentives, however, depend on the profits of all firms;  $\Delta W = \Delta\pi_i + \sum_{j \neq i} \Delta\pi_j + \Delta S$ .

**PROPOSITION 9:** *When the increase in compatibility leads to less-than-industrywide compatibility, the private incentives to standardize may be excessive.*

### C. The Construction of an Adapter

In the adapter case, a firm unilaterally can act to make its product compatible with those of another network. In contrast with the adoption of an industry standard, if side payments to block compatibility are not feasible, then the adapter will be constructed as long as at least one firm earns increased profits from compatibility. When the compatibility mechanism is an adapter, the most reasonable assumption about the costs of compatibility is that the firm that constructs the adapter is the only one to bear the cost,  $F$ . Thus, firm  $i$ 's private incentive to construct an adapter is  $\Delta\pi_i - F$ , while the social incentive is  $\Delta\pi_i + \sum_{j \neq i} \Delta\pi_j + \Delta S - F$ . The difference,  $\Delta\pi_{-i} + \Delta S$ , may in general be either positive or negative, implying that firm  $i$ 's incentives to construct an adapter may be too low or too high from a social welfare point of view.

To see how the private and social incentives differ, suppose there are only two firms. Since the smaller firm in the initial equilibrium has the most to gain by the move to a symmetric equilibrium with compatibility, we need look only at the incentives of a firm with an initial market share of not more than 50 percent—firm 2, say. Since  $\Delta\pi_2 > \Delta\pi_1$ , the private decision will be to become compatible if and only if  $\Delta\pi_2 > F$ .<sup>10</sup> Compatibility is

<sup>10</sup> We are ignoring the possibility that the firms play a waiting game in which each hopes (in vain) that the

socially optimal if and only if  $\Delta W > F$ . The divergence between the social and private incentives is given by  $\Delta W - \Delta\pi_2 = \Delta\pi_1 + \Delta S$ . By Proposition 4, we know that  $\Delta S > 0$ ; the fact that consumers enjoy some of the benefits of compatibility tends to make the private incentives too low. On the other hand, it is not true in general that  $\Delta\pi_1 > 0$ , so we cannot conclude in general that the private adoption decision is too conservative.

One case in which the private adoption incentives are too low is when the initial equilibrium is symmetric. In that case,  $\Delta\pi_1 = \Delta\pi_2$ , so that if  $\Delta\pi_i > 0$  for one firm, then the change in profits is positive for the other firm as well. As a result,  $\Delta W > \Delta\pi_i$  whenever  $\Delta\pi_i > 0$ , and we have

**PROPOSITION 10:** *Suppose there are only two firms (or coalitions). If the incompatibility equilibrium is symmetric and there are no side payments, then the private incentives to construct an adapter are too low.*

When there are only two coalitions, permitting side payments to share the costs of the adapter would promote efficiency when the incompatibility equilibrium is symmetric. The adapting coalition confers benefits both on its rival, which free rides on compatibility, and on consumers. Side payments can help solve the free-riding problem, but (by Proposition 6) still leave the firms with insufficient incentives.

When the incompatibility equilibrium is asymmetric, it is possible that the initially larger firm (which does not build the adapter) loses so much market share when the smaller firm builds an adapter that its profits fall, that is,  $\Delta\pi_1 < 0$ . If this effect dominates the increase in consumers' surplus, that is, if  $\Delta\pi_1 + \Delta S < 0$ , then  $\Delta W < \Delta\pi_2$  and firm 2's compatibility incentives are excessive. The increase in firm 2's market share at the expense of firm 1 is a private gain for which there is no corresponding social benefit.

**PROPOSITION 11:** *Suppose there are only two coalitions. A coalition with an incompatibility market share of less than 50 percent may have socially excessive incentives to construct an adapter.*

This result is most likely to obtain when the incompatibility equilibrium entails one coalition having a very small market share, as in the monopoly equilibrium.

When the means of achieving compatibility is the construction of an adapter, one firm may attempt to make the networks compatible even though the other firms would prefer that the networks remain incompatible. In such cases, the latter firms may be willing to make expenditures to block compatibility, perhaps through legal channels (currently, there are numerous court cases involving video game and personal computer compatibility). It is not possible to say in general whether such expenditures promote or diminish efficiency. In some cases,  $\Delta\pi_1 < 0$ ,  $\Delta\pi_2 > F$ , and  $\Delta W < F$  as noted in Proposition 11, and firm 1's ability to block the adapter will raise efficiency (if the blocking costs themselves are not too high). In other cases,  $\Delta\pi_1 < 0$ ,  $\Delta\pi_2 > F$ , and  $\Delta W > F$ , so blocking the adapter would reduce social welfare, even if the blocking costs are zero. For a given cost and demand structure, one can determine whether  $\Delta W$  exceeds  $F$  or not, but it is not possible to determine this relationship simply on the basis of  $\Delta\pi_2$  exceeding  $F$ .

#### D. Extensions and Generalizations

We have made some restrictive assumptions in order to simplify our analysis of the incentives for network compatibility. It is useful to put the results that we have obtained into perspective by discussing the general nature of the divergence between the social and private incentives to achieve compatibility. Essentially, there are two sources of distortion. In making its compatibility decision, each firm ignores the effects that this move will have on: 1) the level of consumers' surplus; and 2) the profits of the other firms.

---

other will build an adapter even though each would privately benefit from building the adapter itself.

Consider the first effect. When the move to compatibility raises consumers' surplus, the firms' incentives tend to be too low. Conversely, when the move to compatibility lowers consumers' surplus, the firms are biased towards compatibility. The change in consumers' surplus can itself be decomposed into two components: (a) the change due to the shift in the level of total output; and (b) the change that arises when the marginal consumer values the network externality differently than does the average consumer.

(a) The level of consumers' surplus is an increasing function of the level of total output. When the only costs of compatibility are fixed, we showed that the move to complete compatibility raises output and, hence, consumers' surplus. In this case,  $\Delta\pi$  is less than  $\Delta W$ . Once we relax the assumption that the move to compatibility has no impact on marginal costs, however, output may be lower with complete compatibility than without. The adoption of an industry standard or the construction of an adapter will necessitate the redesign of some or all of the products, which may lead to shifts in the variable costs of production (either upwards or downwards). Whereas the fixed costs of compatibility do not affect the equilibrium output level, changes in marginal costs do. In particular, when the increase in marginal costs is sufficiently large relative to the network effects, total output will be lower under complete compatibility than under incompatibility. In these cases, consumers' surplus will fall as a result of the move to complete compatibility and  $\Delta\pi$  is greater than  $\Delta W$ —the firms' joint incentive are excessive.<sup>11</sup>

<sup>11</sup>In fact, when compatibility raises producers' marginal costs, the firms may use the move to compatibility *solely* as a coordinating device to reduce their joint output (i.e., they may have incentives to make their products compatible even if there are no network externalities). This result is an example of the general theory of cost-based facilitating practices (see Steven Salop and David Scheffman, 1983; Katz and Harvey Rosen, 1985; and Jesus Seade, 1983): in an oligopoly, all firms may benefit from jointly increasing their costs because it induces them to reduce their collective output, which may raise their revenues by more than the increase in costs.

(b) The level of consumers' surplus also depends on the relationship between the marginal and inframarginal consumers' valuations of the good. For a given level of output, the firms must set prices low enough to attract the marginal consumer. The lower is the marginal consumer's valuation relative to the average consumer's valuation, the larger will be consumers' surplus.

In our model, all consumers value the network externality equally, and all consumers' valuations of the good rise equally when compatibility is achieved. Thus, for a fixed level of output, the firms can raise prices by just this amount and consumers' surplus is unaffected. More generally, consumers may differ in their valuations of the network externality. If the network externality is stronger for the marginal consumer, then the move to compatibility will raise his or her willingness to pay for the good by more than that of the average consumer. For a given level of output, the firms will be able to raise the price by more than the increase in the average consumer's willingness to pay for the product. Consumers' surplus will fall, and the joint private incentives will tend to be greater than the social incentives. Of course, if the network externality is smaller for the marginal consumer, then the bias will run in the other direction.<sup>12</sup>

The change in consumers' surplus puts a wedge between the change in joint profits and the change in total welfare. When side payments are not feasible, the decision to achieve compatibility depends on the individual profit levels of the firms, and there is a second wedge. The change in profits may be positive for some firms and negative for others. As we have shown, the relationship between the changes in firms' profits will depend on two factors. First, it will depend on their relative changes in market shares

<sup>12</sup>It is straightforward, but messy, to extend our model in this direction. There is nothing about this particular problem that is intrinsic to networks. For discussion of the general inability of prices to convey information about the preferences of inframarginal consumers, see A. Michael Spence (1975) and the references cited therein.

and revenues in moving to compatibility. When one group of firms gains market share and profits at the expense of another, the first group will be biased towards compatibility and the latter will be biased away from it. Second, the relationship will depend on the relative costs of compatibility that the producers incur. When the costs of compatibility fall more heavily on some firms than on others, there is a free-rider problem that tends to bias the firms away from compatibility.<sup>13</sup>

#### IV. Conclusion

We have developed a simple model to capture what we believe is a very significant element of competition in several important markets. Despite this simplicity, some general points emerge. First, the structure of the equilibria in our model confirms the importance of consumers' expectations in markets where network externalities are present. We have subjected expectations to a rationality constraint, but the expectations formation process remains an important element of the market to model explicitly. Given the possibility of multiple equilibria when products are incompatible, firms' reputations may play a major role in determining which equilibrium actually obtains. For example, the existence of a strong reputation for being a market share leader may explain IBM's rapid rise to preeminence in the personal computer market. It would also be useful to consider firms' expenditures to influence consumers' expectations, such as precommitments to a given level of software.

Turning to the compatibility decisions, although we would not want to draw policy conclusions at such an early stage in the analysis, our model does point to areas in which public policy can have an important impact. We have shown that the private decision will depend crucially on the decision locus (whether firms can act unilaterally or if consensus is required) and on the feasibility

of side payments. Public policy can influence both of these features. Patent and copyright laws are a significant determinant of whether the compatibility technology is better modeled as the joint adoption of an industry standard (when patents are strictly and broadly enforced), or as the unilateral construction of an adapter (when they are loosely enforced or narrowly applied). From Proposition 1, we know that if the costs of adapting are negligible, and there are no other entry barriers, the market will be perfectly competitive.<sup>14</sup>

Allowing firms to make side payments also may influence the likelihood of compatibility being adopted—upwards when the technology is an industry standard, and either upwards or downwards when the compatibility technology is an adapter. The discussion in Section III, Part D, also points out the need for policymakers to scrutinize the form of the side payments or royalties. Per unit charges may have the effect of implicit cartels by inducing outputs contractions. Finally, public policy can affect the costs of compatibility. Antitrust exemptions that allow industry groups to get together may lower the costs of achieving compatibility and thus make it more likely.

The model here is only a beginning. Explicitly dynamic, multiperiod models are needed to shed additional light on the behavior of markets in which network externalities are important. We hope that this paper will encourage further research in the area of network competition and public policy towards compatibility.

#### APPENDIX

In the text, we have examined a model where a firm's announcement of its planned level of output has no effect on consumer expectations. This model can be viewed as

<sup>13</sup>Here we are assuming that when the compatibility technology is an adapter, the costs fall more heavily on the adapting firm.

<sup>14</sup>This outcome may not be the socially optimal one. Absent the ability to earn rents from its network size (through incompatibility), a firm may not have incentives to make the investments necessary to obtain the network. The issues are exactly analogous to those encountered in the analysis of optimal patent policy.

one in which the firms are unable to commit themselves, so that only the output levels of the *FECE* are credible announcements. In this Appendix, we consider the opposite polar case in which firms *can* commit to announced output levels before consumers make their purchase decisions. Firm *i* commits itself to output level  $x_i$  and consumers make their purchase decisions by looking at  $v(y_i) - p_i$  across all brands. Firm *i* chooses its level of output taking the output level of the other firms as given. Thus, we have a standard Cournot equilibrium with demand-side economies of scale.

Given total output  $z$  and firm output  $x_i$ , firm *i* has profits of

$$x_i \{ A + v(y_i) - z \}.$$

Differentiating with respect to  $x_i$ , the first order conditions are

$$(A1) \quad A + v(y_i) - 2x_i - \sum_{j \neq i} x_j + x_i v'(y_i) = 0 \quad \text{for } i = 1, 2, \dots, n.$$

The only difference between equation (A1) and our earlier first-order condition is the addition of the term  $x_i v'(y_i)$ . This term captures the fact that firm *i* can directly influence consumers' expectations regarding its network size.  $x_i v'(y_i)$  is positive, so that firm *i*'s reaction curve will shift upwards in comparison with the earlier equilibrium reaction correspondence.

The analysis is essentially unchanged from that in the text; we simply substitute  $v(y_i) + x_i v'(y_i)$  for  $v(y_i)$  in firm *i*'s reaction function. Some additional assumptions on  $v$  are necessary to ensure that this substitute function is itself concave. In the case of complete incompatibility ( $y_i = x_i$  for all *i*), and a constant elasticity network externality function

$v(x) = \beta x^\alpha$ , we simply replace  $v(x) = \beta x^\alpha$  by  $v(x) + xv'(x) = \gamma x^\alpha$ , where  $\gamma = (1 + \alpha)\beta$ .

Qualitatively, the "commitment" equilibria differ from those analyzed in the text in the following ways. 1) Each firm's reaction correspondence becomes a reaction function, since it can "choose"  $x_i^e$  as well as  $x_i$  (see the discussion of Figure 2 in Section II, Part B). 2) Equilibrium entails greater output, as each firm accounts for the  $x_i v'(y_i)$  term, which shifts its reaction curve outwards. 3) No longer can a firm make greater profits in the  $k + 1$ -active-firm equilibrium than in the  $k$ -firm equilibrium.

# Asymmetric Information and Collusive Behavior in Auction Markets

By JONATHAN S. FEINSTEIN, MICHAEL K. BLOCK, AND FREDERICK C. NOLD\*

We present a theoretical and empirical analysis of the behavior of a bidder's cartel in a multiperiod auction market in which the purchaser is relatively uninformed. Our work establishes a tentative connection between the economics of information and collusion by concentrating on the cartel's informational monopoly, and its ability to both increase profits and mask its presence by passing misinformation to the purchaser.

In the models we develop, costs are assumed to be stochastic, and projects awarded in adjacent periods to be substitutes for one another. As a result, the purchaser will have incentive to intertemporally reallocate his demand, buying more or less of the current period's project, depending upon whether the current market price is lower or higher than the price which he expects to prevail in the future. A purchaser who needs to form such price expectations, yet is ignorant about production costs and market structure, will be particularly attracted to the auction mechanism, because the data contained in past auctions' bids can apparently be incorporated into an explicit structural model of expected future price. In fact, such a purchaser may hold auctions frequently merely to acquire information.

Such pleasant appearances are deceiving. Once the auction's bidders become aware of the informational use to which their bids are being put, they will have incentive to form a cartel, thereby extracting a premium for their

knowledge by misinforming the purchaser and skewing his intertemporal decision making to their advantage.

In some respects the mechanics of our model resemble the case of a multiproduct monopolist selling goods that are substitutes for one another. What is unique to our analysis is the dependence of one of the goods, future demand, on price expectations, which are an information resource. We are suggesting that information that is distributed asymmetrically among market participants is susceptible to the inefficiencies of collusion. In some ways the implications of our work are considerably stronger than this, because our cartel never reveals its true knowledge, and thus our market may be more inefficient than more standard monopolies, in which the good is always traded, albeit at noncompetitive prices. Furthermore, by explicitly modeling the purchaser's rational structural approach to price forecasting, we point out that complete rational expectations models may be more susceptible to exploitation by informational cartels than simpler forecasting techniques.

We have tested the implications of our model in a case study of North Carolina highway construction cartels. The highway construction industry is an auction market characterized by government procurement agencies who are uninformed relative to suppliers, and comes complete with a substantial record of known collusion in recent years. Thus it seems an ideal hunting ground for verification of our theoretical findings.

Our paper proceeds as follows. In Section I, we model a multiperiod competitive auction market, and describe a Bayesian mechanism through which the purchaser uses past data to improve the accuracy of his price expectations. Section II establishes theoretical results for the bidders' cartel which has incentive to form in this market: we describe

\*Massachusetts Institute of Technology, Cambridge, MA 02109 and University of Arizona, Tucson, AZ 85721, respectively. Nold was formerly of Rhodes Associates and is now deceased. Part of this research was supported under research grant 81-IJ-CR0062 from the National Institute of Justice.

the specific strategies through which the cartel can misinform the purchaser, characterize the cartel's optimal short-run and long-run behavior, and mention extensions to our basic model. Section III presents our empirical results in highway construction, and some conclusions are offered in Section IV.

### I. The Auction Model

We begin the presentation of the formal model of our multiperiod auction market by summarizing its important features.

In a typical period  $t$ , a single purchaser solicits sealed bids that represent unit-cost offers on the period  $t$  project. After receiving the bids, the purchaser chooses the quantity, if any, of the period  $t$  project that he will purchase, and also decides whether or not to expend the fixed costs of holding an auction in period  $t + 1$ . Expected costs are identical across bidders and periods.<sup>1</sup> In addition, costs stochastically fluctuate, and as a result, the low bids received in different periods will fluctuate. We assume that projects in adjacent periods are partial substitutes for one another; hence, the purchaser will intertemporally substitute demand between periods in response to fluctuations in the low bid, and so his demand for period  $t$ 's project will depend not only on the period  $t$  low bid, but also on his expectation of period  $t + 1$ 's low bid. Since project costs are correlated, the purchaser can effectively use the information contained in earlier auctions' bids in forming his expectation of the period  $t + 1$  low bid.

To proceed, we define:

$v_t^i$  = the  $i$ th bidder's valuation of the unit cost of the period  $t$  project,

$Q_t$  = the quantity demanded by the purchaser in period  $t$ ,

$b_t^i$  = the  $i$ th bidder's bid in period  $t$ ,

$e_t$  = the purchaser's estimate of the low bid expected in period  $t$ , where  $e_t$  is formed

after the period  $t - 1$  bids have been submitted,

$P_t$  = the purchaser's decision whether or not to hold an auction in period  $t$ , with  $P_t$  made after the period  $t - 1$  bids have been submitted,

$R_t$  = the pool of available bidders in period  $t$ ,

$N_t$  = the number of actual bidders in period  $t$ ,

$m_t$  = the mean of the valuations  $v_t$  in period  $t$  where

$$m_t = \frac{1}{N_t} \sum_{i=1}^{N_t} v_t^i,$$

$s_t^2$  = the variance of the valuations  $v_t$  in period  $t$  where

$$s_t^2 = \frac{1}{N_t - 1} \sum_{i=1}^{N_t} (v_t^i - m_t)^2.$$

Note that our assumption that bidders will supply any quantity at their unit price bid is, in one context, equivalent to the specification of a constant marginal cost technology.<sup>2</sup>

The underlying uncertainty in our model arises because costs stochastically fluctuate around a fixed value. Specifically, bidders unit valuations  $v_t^i$  are independently drawn from a common distribution  $f$  (with cumulative distribution function  $F$ ) according to the rule:

$$(1) \quad v_t^i = \bar{p} + z_t^i \quad \text{where } \bar{p} \text{ is a constant,}$$

$$\text{and } z_t^i \sim N(0, \sigma_p^2).$$

The mean  $\bar{p}$  is identical across periods and bidders, relating cost estimates of projects awarded in different periods. The  $z_t^i$  represent idiosyncratic fluctuations in bidders' unit costs. Such fluctuations are assumed to result both from the transitory cost advantages and disadvantages of specific bidders, and from the specific attributes of the period  $t$  project.

<sup>1</sup>Our empirical work deals with highway construction, where each construction project has many line item components. Projects will often have common line items, correlating their overall values.

<sup>2</sup>If the bidder knows the purchaser's demand function, the open offer may be consistent with a nonconstant cost technology.

Since the  $z_t^i$  are normally distributed as  $N(0, \sigma_p^2)$ , the  $v_t^i$  are also normally distributed as  $N(\bar{p}, \sigma_p^2)$ .<sup>3</sup> We will assume that both the purchaser and suppliers are aware that the  $v_t^i$ s follow a normal distribution, but are ignorant of the true cost parameters  $\bar{p}$  and  $\sigma_p^2$ .<sup>4</sup> In fact, it is this ignorance that makes information acquisition a useful economic activity in this market.

Before continuing, we will without loss of generality (see, for example, Charles Plott, 1980) reorder the valuations  $v_t$  and the bids  $b_t$  such that  $v_t^i$  represents the  $i$ th lowest valuation, and  $b_t^i$  the  $i$ th lowest bid.

The fact that costs are stochastic, along with our assumption that projects awarded in adjacent periods are partial substitutes for one another, leads the purchaser to intertemporally allocate his demand in such a way that he buys a lot in periods when the low bid is unusually low, reflecting low costs, and buys less when the low bid is unusually high, reflecting high costs. In particular, the purchaser's choice of  $Q_t$  depends not just on the period  $t$  unit price,  $b_t^1$ , but also on the expected price in period  $t+1$ , which we denote  $e_{t+1}$ . Hence  $Q_t = Q(b_t^1, e_{t+1}; Q_{t-1})$ .<sup>5</sup> When  $b_t^1$  rises relative to the future price

$e_{t+1}$ ,  $Q_t$  falls, so that  $Q_1 < 0$ ; conversely, when the future price  $e_{t+1}$  rises relative to  $b_t^1$ ,  $Q_t$  rises; hence  $Q_2 > 0$ . Moreover, we will assume that  $Q$  is bounded for all pairs  $(b_t^1, e_{t+1})$ , and that there exists a bid  $b_t^0$  such that  $Q(b_t^0, e_{t+1}; Q_{t-1}) = 0$ .

In addition to choosing  $Q_t$  in period  $t$ , the purchaser must also decide whether or not to expend the fixed costs necessary for holding an auction in period  $t+1$ . This decision,  $P_{t+1}$ , will in part depend upon how much the purchaser hopes to buy next period, which in turn depends upon both  $e_{t+1}$  and  $Q_t$ ; that is,  $P_{t+1} = P(e_{t+1}, Q_t)$ . We assume  $P_1 < 0$ ,  $P_{11} < 0$  ( $P$  convex in  $e_{t+1}$ ),  $P_1(b_t^1, Q_t) = 0$ ,  $P_2 < 0$ , and that some  $x$  exists such that for all  $e \geq x$ ,  $P(e, Q_t) = 0$ .

Thus far in the description of our auction market we have pointed out that stochastic fluctuations in cost create an incentive for purchaser intertemporal substitution, and that this intertemporal substitution depends upon the comparison of the current market price,  $b_t^1$ , to the expected future price,  $e_{t+1}$ . We would now like to further point out that it is these very same stochastic cost fluctuations that cause  $e_{t+1}$  to be uncertain, and thus provide incentive for our purchaser to extract the information contained in each period's bids in order to improve his estimation of  $e_{t+1}$ . In fact, much of the remainder of this paper will be concerned with how the purchaser forms this estimate, and the consequences of the estimate for the economic behavior of the suppliers.

Since the underlying cost variables in our market,  $\bar{p}$  and  $\sigma_p^2$ , are stationary over time, each period's bids will improve the purchaser's ability to estimate  $e_t$  by providing him with "another round" of information. Thus, we choose a Bayesian update mechanism as the most natural method of modeling the purchaser's estimation procedure. We define  $g_t \sim N(\theta_t, \sigma_t^2)$  (with cumulative distribution function  $G_t$ ) to be the purchaser's best approximation to the cost density  $f$  following the submission of the period  $t$  bids, and  $\hat{N}_{t+1}$  to be the expected number of bidders in period  $t+1$ . We present the mathematical details of the Bayesian mechanism in the Appendix; however, we sum-

<sup>3</sup> Many of our results in fact apply to a much wider class of distributions.

<sup>4</sup> At this point it might be useful to distinguish between what we call production information and market information. For our purposes, the former is information on  $\bar{p}$  and  $\sigma_p^2$  represented by direct observation of the production process, while the latter is information on these parameters obtained from observations on market prices. In the case below we restrict our formal analysis to asymmetric market information—an asymmetry that in fact is produced by our cartel. While it is likely that there is a significant asymmetry in production information between the buyer and his suppliers, it is not required for our analysis of cartel behavior. Asymmetry in production information may, however, be useful, as we indicate in the introduction, in understanding the underlying structure of the problem.

<sup>5</sup> We are ignoring questions of risk and are assuming that the purchaser avoids the complexity of working the entire  $Q$  distribution. Note that  $Q_t$  also depends on  $Q_{t-1}$ , because when  $Q_{t-1}$  has been large,  $Q_t$  tends to be lower since the purchaser's cumulative demand over several periods is downward sloping.

marize the mechanism by the expression for  $e_{t+1}$ :

$$(2) \quad e_{t+1} = b\left(\hat{N}_{t+1}, \int_0^\infty x \hat{N}_{t+1} [1 - G_t(x)]^{\hat{N}_{t+1}-1} g_t(x) dx\right),$$

where  $b(\cdot)$  is a function relating the expected low valuation to the expected low bid. Note that  $b(\cdot)$  depends not only on the low valuation, but also directly on the expected number of bidders. This is the case because when bidders follow Nash noncooperative strategies in the auction, they will shade their bids upwards in an amount dependent upon the number of rival bids anticipated.<sup>6</sup>

It is clear from (2) that the expected number of bidders in period  $t+1$ ,  $\hat{N}_{t+1}$ , is a major determinant of the expected low bid,  $e_{t+1}$ . Much of the previous auction literature has exogenously specified the number of bidders in the market; we propose to improve upon this approach by determining  $\hat{N}_{t+1}$  endogenously in our model as a function of expected market demand,  $\hat{Q}_{t+1}$ . In fact, due to purchaser intertemporal substitution, expected long-run demand will often not equal expected short-run demand, and so we make a distinction between 1) the available pool of bidders in period  $t+1$ , which consists of suppliers who have made a long-run decision to enter the market, and 2) the number of suppliers out of this available pool who actually submit bids in period  $t+1$ .

The available pool of bidders consists of suppliers who have entered the market, and expect to remain for several periods. The equilibrium number in this pool will be a function of the long-run expected demand in the market as of period  $t$ ,  $Q(e_{t+1}, e_{t+1})$ , which represents demand at the price  $e_{t+1}$ , devoid of any short-run substitution effects. Specifically, the equation relating current

market conditions to the expected pool of bidders is assumed to be of the form:

$$(3) \quad \hat{R}_{t+1} = R_t + r(Q(e_{t+1}, e_{t+1}), R_t), \\ r_1 \geq 0, \quad -1 \leq r_2 \leq 0.$$

Equation (3) implicitly distinguishes between the behavior of the  $R_t$  suppliers already in the bidders pool and potential entrants. This is a valid distinction when there are assumed to be fixed costs of entry and exit.

We will presume that for each  $e_{t+1}$  there exists an equilibrium pair  $(Q^*, R^*)$  such that  $r(Q^*, R^*) = 0$ , and  $\hat{R}_{t+1} = R_t$ .<sup>7</sup> Furthermore, since entry or exit requires a fixed cost,  $r_1(Q^*, R^*) = 0$ . That is, small fluctuations in  $Q$  around its equilibrium value will not induce suppliers to change status. In specifying (3) we assume that while the industry is constant cost there is a minimum scale of operation. Hence given that "all firms are created equal," as  $Q(e_{t+1}, e_{t+1})$  rises, the number of bidders in the pool that can successfully survive also rises.

When there are fixed costs of determining the valuations  $v$ , the actual number of suppliers bidding in period  $t+1$ ,  $N_{t+1}$ , will generally not equal  $R_{t+1}$ , but instead will fluctuate because of purchaser intertemporal substitution. Specifically, if we summarize the period  $t+1$  demand curve as  $\hat{Q}_{t+1}$ , expected demand in period  $t+1$ , then the equation for the number of bidders expected in period  $t+1$  will be of the form:

$$(4) \quad \hat{N}_{t+1} = n(\hat{Q}_{t+1}, \hat{R}_{t+1}),$$

where  $n_1 > 0, n_2 > 0$ .

Equation (3) states that  $\hat{N}_{t+1}$  depends upon  $\hat{Q}_{t+1}$ ; we have already specified that  $\hat{Q}_{t+1}$  depends upon  $e_{t+1}$ , and that  $e_{t+1}$  in turn depends upon  $\hat{N}_{t+1}$ . Thus the three variables  $e_{t+1}$ ,  $\hat{Q}_{t+1}$ , and  $\hat{N}_{t+1}$  are interdependent and

<sup>6</sup>John Riley and William Samuelson (1981) have explicitly calculated the Nash function  $b(\cdot)$  and its embedded shading. It is of the form

$$b_i^j = v_i^j + \int_0^{v_i^j} F^{\hat{N}_i-1}(x) dx / F^{\hat{N}_i-1}(v_i^j).$$

<sup>7</sup>We say "equilibrium pair" because while  $Q$  affects the number of suppliers,  $R$  will also affect  $Q$  through its effect on  $N$  (see below).

must be simultaneously determined for our auction market to reach equilibrium in period  $t + 1$ .

Our auction market is now fully described, and the description thus far is an accurate portrayal of the market under competitive conditions. However, since the major point of our next section will be to show how a bidders' cartel can drive an informational wedge between itself and the purchaser, it is appropriate to mention the informational aspects of this market that are vulnerable to a cartel. First, the purchaser uses past bids to estimate the market's underlying cost parameters  $\bar{p}$  and  $\sigma_p^2$ , as well as the pool of bidders,  $R_t$ ; as a result manipulation of bids can bias his estimates. Second, equation (4) describes a short-run entry and exit equation that affects the future expected price,  $e_{t+1}$ . Since a cartel can control who bids, it can mislead the purchaser about the sensitivity of entry and exit to  $e_{t+1}$  by mimicking the form of (4) with a "bogus" equation of its own choosing.

## II. Theoretical Results

We have provided a set of behavioral equations that describe the functioning of our auction market under competitive conditions. Central to this description is the purchaser's use of the information contained in past auctions to improve his forecast of the future market price. To the extent that the purchaser is successful in applying the knowledge he gains from past auctions to the prediction of future price, he gains informational market power relative to the bidders in that he can more effectively manage his demand over time. As a result, the assumption that the auction market is competitive is suspect, because it implies that the auction's bidders collectively provide the purchaser with a "free lunch" consisting of their private valuations of project costs and market conditions. Economic theory suggests that such a free lunch will scarcely outlast breakfast. Rational bidders will find a means of either charging the purchaser a premium for their knowledge, or, preferably, consistently misinforming him and so preserving their informational advantage.

In this section we will demonstrate that, by forming a bidders' cartel, the auction participants can intentionally pass the purchaser misinformation about both project costs and the short-run entry and exit behavior of suppliers. Monopolizing market information and distorting the purchaser's view of the auction market will allow the cartel to achieve extraordinary profits, even by cartel standards, and will in addition mask the cartel's presence and so minimize the chances of the cartel being detected. In fact, as our argument proceeds, it will become clear that an uninformed purchaser's attempt to generate market information through the auction mechanism actually encourages the formation of a cartel.

We assume that all available bidders enter the cartel, and we concentrate on total cartel profits rather than the apportionment of these profits to specific cartel members. Our analysis of the bidders' cartel proceeds in several steps. We begin by showing that by manipulating the three variables  $R_t$ ,  $m_t$ , and  $s_t^2$ , the cartel can successfully alter the purchaser's perception of next period's low bid,  $e_{t+1}$ . Next we discuss the cartel's optimal choice of  $e_{t+1}$  and the low bid,  $b_t^1$ ; this discussion is divided into several parts, first an existence proof, then a demonstration of a standard period-by-period monopoly as a point of comparison with our more sophisticated cartel, and finally a detailed presentation of our cartel's short- and long-run strategies. Following this, we consider a more general cost scenario in which  $\bar{p}$  and  $\sigma_p^2$  stochastically range from period to period. As we shall see, this variability introduces additional noise into the auction market and works to the cartel's advantage. Finally, we suggest that by modifying his expectations from a fully rational structural model of the auction market to a simpler adaptive expectations mechanism, the purchaser can reduce his susceptibility to cartel exploitation.

### A. The Cartel's Ability to Manipulate $e_{t+1}$

In our multiperiod auction market, the purchaser extracts the information contained in past auctions' bids through a Bayesian mechanism and applies this information to

improved estimation of the expected future market low bid,  $e_{t+1}$ . Thus, the ability of a bidder's cartel to pass the purchaser misinformation about project costs and market conditions depends upon its ability to alter bids in such a way as to affect the purchaser's estimate of  $e_{t+1}$ . In our model the three variables through which the period  $t$  bids affect the purchaser's estimate of  $e_{t+1}$  are  $R_t$ ,  $m_t$ , and  $s_t^2$ . Clearly a cartel consisting of all available bidders can arbitrarily pick any or all of these variables in period  $t$ , since it controls who bids and what they bid.

Now suppose the cartel wishes to inflate the purchaser's estimate of  $e_{t+1}$ ; the following theorem shows that this can be accomplished by any one of the three strategies: (a) reducing the number of market suppliers  $R_t$ ,<sup>8</sup> (b) increasing  $m_t$ , or (c) decreasing  $s_t^2$ :

**THEOREM 1: Simple Cartel Information Strategies.** *The cartel can inflate  $e_{t+1}$  by (a) reducing  $R_t$ , (b) raising  $m_t$ , or (c) reducing  $s_t^2$ ; that is,  $\partial e_{t+1}/\partial R_t < 0$ ,  $\partial e_{t+1}/\partial m_t > 0$ , or  $\partial e_{t+1}/\partial s_t^2 < 0$ . The case in which the cartel wishes to deflate the purchaser's estimate of  $e_{t+1}$  is identical. (For proof, see Appendix II.)*

Theorem 1 demonstrates that the cartel can essentially manipulate  $e_{t+1}$  by manipulating  $R_t$ ,  $m_t$ , or  $s_t^2$ . Obviously the cartel can do the same by manipulating a combination of all three variables. In fact, since the cartel has at its disposal three "instrumental" variables with which to affect only one endogenous variable, it will, each period, have its choice from a wide range of alternative combinations of  $R_t$ ,  $m_t$ , and  $s_t^2$  in manipulating the purchaser's estimate of  $e_{t+1}$ .

Note that Theorem 1 forms the basis of the empirical tests of our model in the highway construction industry, which we present

in Section III. We have found strong evidence consistent with the view that highway bidders' cartels actually use these strategies to misinform government procurement agencies.

### B. The Cartel's Choice of $b_t^1$ and $e_{t+1}$

Having shown that the cartel can in effect "choose"  $e_{t+1}$  for the purchaser, we turn our attention to the cartel's maximization problem, its choice of an optimal  $b_t^1$  and  $e_{t+1}$ . To begin our analysis of this process we express total cartel profits from period  $t$  onwards as

$$(5) \quad \pi_t = Q_t(b_t^1 - v_t^1) + \sum_{i=1}^{\infty} \frac{P_{t+i}Q_{t+i}(b_{t+i}^1 - v_{t+i}^1)}{(1+\delta)^i},$$

where  $\delta$  is the cartel's discount factor. Since  $Q$  is bounded from above and below, and  $P$  effectively bounds  $e$  (i.e.,  $y$  exists such that for  $e > y$ ,  $P(e, Q) = 0$ ), the sum on the right of the right-hand side of (5) will be finite—we will denote it as  $J(b_t^1, e_{t+1})$ .

Formally, the cartel's maximization problem is

$$(6) \quad \text{Max}_{b_t^1, e_{t+1}} Q_t(b_t^1, e_{t+1}; Q_{t-1})(b_t^1 - v_t^1) + J(b_t^1, e_{t+1}).$$

Since  $Q$  is bounded, the implicit constant marginal cost technology of the suppliers implies that a well-defined interior solution exists to this problem:

**THEOREM 2: Existence Theorem.** *In period  $t$ , an optimal cartel choice of  $(b_t^1, e_{t+1})$  exists.*

(This is a standard nonlinear programming result; therefore, we omit the proof.)

In order to relate the behavior of our bidders' cartel to existing theories of collusion, we begin our analysis of (6) by discussing the limiting case in which purchaser decisions are made independently of  $e_{t+1}$ , which will be the case when there is no intertemporal substitution,  $\partial Q/\partial e = 0$ , and auctions

<sup>8</sup>In our formulation  $N_t$ , the actual number of bidders in period  $t$ , does not affect period  $t+1$ , whereas  $R_t$ , the number of suppliers, does, because of fixed entry and exit costs. However,  $R_t$  is in some sense unobservable, and must be extrapolated from the behavior of  $N_t$  over several periods. For a further discussion of this point see our empirical work in Section III.

are guaranteed to be held every period, so that  $P_t = 1$  for all  $t$ . In this situation, auctions held in different periods have no effect on one another, and so, in period  $t$ , the cartel faces a standard single-period monopoly market and will only be concerned with choosing the single variable  $b_t^1$ . Hence  $b_t^1$  will equal the standard monopoly price  $b_t^m$ , which will depend upon the unit marginal cost  $v_t^1$ , and the purchaser's demand function  $Q_t(b_t^1)$ . Formally, the problem is simply,

$$(7) \quad \pi_t = \text{Max}_{b_t^1} Q_t(b_t^1)(b_t^1 - v_t^1),$$

and the  $J$  function is independent of  $b_t^1$ .

When the purchaser's elasticity of substitution between periods is significant, and  $P_t$  is free to vary, a profit-maximizing cartel will not ignore the effect of  $e_{t+1}$  on profits  $\pi_t$ . In fact, by distorting the purchaser's perception of  $e_{t+1}$ , the cartel can earn significantly higher profits than the standard single-period monopoly case we have just outlined.<sup>9</sup> We will characterize this complete model, in which the cartel chooses both  $b_t^1$  and  $e_{t+1}$ , by considering the cartel's short- and long-run strategies separately.

### C. Short-Run Cartel Behavior

When the bidders' cartel first begins operating in our auction market, it will raise both  $b_t^1$  and  $e_{t+1}$  towards their monopoly levels. In the simple model we have presented, if the cartel were to set  $e = b^1$ , then it would face no risk either of detection or of the purchaser abandoning his structural model. In fact, however, the cartel will begin by inflating  $e_{t+1}$  above  $b_t^1$ , fooling the purchaser into believing that period  $t$ 's low bid is lower than period  $t+1$ 's low bid will be, and inducing the purchaser to substitute future demand forward into period  $t$ . Then, in period  $t+1$ , the cartel will inflate  $e_{t+2}$  above  $b_{t+1}^1$ , washing out the negative substitution from period  $t+1$ , again misleading the purchaser

into believing that the current market price is lower than the expected future market price. We will consider the "short run" to consist of the periods during which the cartel engages in this practice of setting  $e$ 's above  $b^1$ 's.

How long the short run lasts will depend on the cartel's perception of when the purchaser becomes suspicious about the discrepancy between  $e$  and  $b^1$ . We will concentrate on the first period.

In our model, during the cartel's first period it will set  $e$  near its upper bound, which is the value of  $e$  at which the purchaser is indifferent about holding next period's auction.<sup>10</sup> To see why increasing  $e_{t+1}$  above  $b^1$  increases profits, differentiate (6) with respect to  $e_{t+1}$ :

$$(8) \quad \frac{\partial \pi_t}{\partial e_{t+1}} = \frac{\partial Q_t}{\partial e_{t+1}}(b_t^1 - v_t^1) + \frac{\partial J}{\partial e_{t+1}}.$$

In the short run,  $e$  can be reset in period  $t+1$ ; as a result, all aspects of the  $J$  function will be independent of  $e_{t+1}$  except  $P_{t+1}$ , the decision about holding next period's auction, and  $\hat{Q}_{t+1}$ . Hence:

$$(9) \quad \left. \frac{\partial \pi_t}{\partial e_{t+1}} \right|_{SR} = \frac{\partial Q_t}{\partial e_{t+1}}(b_t^1 - v_t^1) + P_t \frac{\frac{\partial \hat{Q}_{t+1}}{\partial e_{t+1}}(b_{t+1}^1 - v_{t+1}^1)}{1 + \delta} + \frac{\partial P_t}{\partial e_{t+1}} \frac{\hat{Q}_{t+1}(b_{t+1}^1 - v_{t+1}^1)}{1 + \delta}.$$

Since  $P_t$  is convex,  $P$  will remain at 1 for small changes in  $e$ , hence  $\partial P_t / \partial e = 0$  for  $e$  near  $b^1$ . In addition, since  $e$  will be reset in  $t+1$ ,  $\hat{Q}_{t+1}$  depends on  $P_{t+1}$  only because of the constraint on total purchaser demand across several periods (i.e.,  $Q_t + Q_{t+1}$  must not exceed some bound on demand); as a

<sup>9</sup>The mechanism lying behind this claim is the cartel's ability to shift the purchaser's demand curve in or out by manipulating  $e_{t+1}$  in response to variations in cost.

<sup>10</sup>In a more complete model, the risk of detection will induce the cartel to choose  $e$  at some interior point between  $b^1$  and  $e$ 's upper bound.

result,  $\hat{Q}_{t+1}$ , which is discounted at  $1 + \delta$ , will never fall more than one-for-one with  $Q_t$ . Thus, (9) will generally be positive.

We now turn to the question: what is the cartel's preferred way of manipulating  $e$ ? In the short run, reducing the variance of bids is the most effective way of influencing  $e$ , because it not only directly lowers the purchaser's variance estimate  $\sigma_{t+1}$ , but also increases the weight the purchaser attaches to the current period's bids relative to his prior estimates. This implication that a cartel will sharply reduce the variance of bids in the short run provides the most direct link with our empirical tests below in North Carolina highway construction.

There are two ways in which our short-run cartel analysis could be significantly extended. First, one would like to predict when and where such a cartel will enter an auction market. Since the cartel must convince the purchaser of a one-time jump in costs, it will presumably pick a situation in which the purchaser has little past data that is relevant to the current auction.<sup>11</sup> Second, the question arises—what costs will the cartel incur should the purchaser abandon his structural model? We suggest some possibilities in Part F below.

#### D. Long-Run Cartel Behavior

As we have pointed out above, in the long run, our bidders' cartel will not be able to consistently inflate  $e$  above  $b^1$  and continually induce forward substitution. The purchaser will eventually realize that his method of estimation is incorrect rather than presuming, as he does in the short run, that he has merely misestimated parameters. In fact, in order to preserve the purchaser's faith in his structural model of the auction market, which is necessary if the cartel is to reap informa-

tional profits,<sup>12</sup> we will assume that the cartel must insure that the bids it submits fulfill the following consistency requirements.

First, on average, the purchaser's estimate of  $e_t$  must be unbiased, that is,

$$(10) \quad \lim_{T \rightarrow \infty} \frac{\sum_{t=0}^T b_t^1}{T} = \frac{\sum_{t=0}^T e_t}{T} = \bar{b}.$$

We note that, as in the short-run case,  $b_t^1$  will be chosen at a monopoly level, although not necessarily at the single-period monopoly price.

Second, since the market's cost and demand structures are known to be stationary, the purchaser's estimates of the mean, variance, and pool of bidders must eventually converge to constant values. Formally,

$$(11) \quad \lim_{\substack{T \rightarrow \infty \\ \varepsilon \rightarrow 0}} P\{|\theta_T - \theta_{T+1}| > \varepsilon\} = 0,$$

$$P\{|\sigma_T - \sigma_{T+1}| > \varepsilon\} = 0;$$

$$\lim_{T \rightarrow \infty} r \left( Q \left( \frac{\sum_{t=0}^T e_t}{T}, \frac{\sum_{t=0}^T e_t}{T} \right), R_t \right) = 0,$$

$$\hat{R}_{T+1} = R_T.$$

Third, whatever estimates the purchaser makes of the form of  $n(\cdot)$  must be consistently met by the market participants:

$$(12) \quad \lim_{T \rightarrow \infty} N_T = n_{\text{estimated}}(\hat{Q}_T, \hat{R}_T).$$

In fact, in the long run, the purchaser will expect the entry and exit equation (12) to fulfill a zero-profit condition. A bidder's expected profits are

$$\frac{\hat{Q}_{t+1}}{\hat{N}_{t+1}} (b_1 - v_1) - \text{fixed costs of submitting a bid.}$$

<sup>11</sup>For example, we would expect cartels to pick situations where there is 1) technological innovation which sharply reduces real costs; 2) a large shift in demand, such as a state decision to embark on a major road-building campaign; 3) a new product, such as the shift in road building to interstates; or 4) a substantial and sustained inflation.

<sup>12</sup>For a demonstration of this fact see Part F below.

If we assume that  $b_1 - v_1$  equals a constant,<sup>13</sup> then requiring that long-run expected profits be zero is equivalent to requiring that  $\hat{Q}/\hat{N}$  converge to a constant value:

$$\lim_{t \rightarrow \infty} (\hat{Q}_{t+1}/(\hat{N}_{t+1})) = \text{constant}.$$

We can now rewrite (12) in a simpler form:

$$(12') \quad \lim_{T \rightarrow \infty} N_T = \hat{N}_T = (\text{constant})(\hat{Q}_T).$$

Thus as  $\hat{Q}$  varies, due to purchasers intertemporal substitution,  $\hat{N}$  must vary proportionately. However, we note that since actual supplier profits are unobservable, the purchaser will not know what value the valid  $\hat{Q}/\hat{N}$  should equal: he will only know that in the long run it should have the same value every auction.

What sort of bids will the cartel submit in the long run? First, consider the choice of  $\bar{b}$ . Notice that by using its informational strategies the cartel can choose  $\sigma$  and  $\theta$  so that when this period's project is the long-run average  $e = \bar{e}$  and  $\bar{e} = \bar{b}$ . Thus, when the low bid is  $\bar{b}$ , the auction market is in a stochastic equilibrium, because next period's expected price is the same as this period's actual price. Thus the purchaser's demand function is  $Q(\bar{b}, \bar{b})$ . The cartel's choice of  $\bar{b}$  is now clear: it will pick  $\bar{b}$  to solve the monopoly problem of maximizing  $(\bar{b} - \bar{v})Q(\bar{b}, \bar{b})$ . We will denote the long-run demand induced by this  $\bar{b}$  as  $Q_A$ , and the expected number of bidders next period, when  $\hat{Q} = \hat{Q}_A$  also  $= Q_A$ , as  $\hat{N}_A$ .

Since the cartel ensures that  $\bar{e} = \bar{b}$ , the market will appear completely consistent with its competitive structure as modeled by the purchaser, and the cartel's presence will remain undetected. In contrast, a cartel that ignores the value of its informational strategies and inflates only  $b_i^1$  to its monopoly level, and not  $e_i$ , will in general fail to satisfy (10). To see this, note that in any period  $b_i^m$

must satisfy a pair of conditions:

$$(13) \quad e_i = b_i^m \quad \text{or} \quad \sigma_i Z_{N_i} + \theta_i = b_i^m;$$

$$(14) \quad b_i^m = \text{Max}_{b_i^1} \pi_i,$$

where  $Z_{N_i}$  is derived from the standard normal power density of Appendix II. Since these conditions do not coincide, the  $b_i^m$  which satisfies (14) and maximizes profits will fail to satisfy (13), unless  $e_i$  is independently adjusted, and hence the average of the  $b_i^m$  over many periods will also fail to equal the long-run  $e$  average. In fact, a cartel which only adjusts  $b_i^1$  will find that  $e_i$ , which includes all bids, will consistently underestimate  $b_i^1$ ; the purchaser will then be tipped off to the presence of a cartel.

Our cartel's ability to hide itself is not its only long-run advantage. Specifically, we can investigate how our cartel bids when the low bid fluctuates around  $\bar{b}$ , due to fluctuations in cost around  $\bar{v}$ . Because unit costs are stochastic, our cartel will find that its unit profit margin is higher when  $b^1$  is below  $\bar{b}$  than when  $b^1$  is above  $\bar{b}$ . As a result the cartel has incentive to skew the purchaser's intertemporal allocation of demand so that he buys more in high-profit/low-cost periods, and less in low-profit/high-cost periods.

We will demonstrate that the cartel can in fact intertemporally reallocate the purchaser's demand in this manner. Note that the purchaser's choice of a pair  $Q_i$  and  $\hat{Q}_{i+1}$  depends on the relative price ratio  $b_i^1/e_{i+1}$ . Figure 1 depicts a set of  $(Q_i, \hat{Q}_{i+1})$  indifference curves and a typical  $b_i^1/e_{i+1}$  relative price line; given the current low bid  $b_i^1$ , the purchaser forms an estimate of  $e_{i+1}$ , and chooses  $Q_i$  and  $\hat{Q}_{i+1}$  at the point of tangency. What is unusual about this utility-maximization problem is that  $e_{i+1}$  itself depends upon  $\hat{Q}_{i+1}$ . Through (4)  $e_{i+1}$  is a function of the parameters  $\theta$ ,  $\sigma^2$ , and  $\hat{N}_{i+1}$  and while  $\theta$  and  $\sigma^2$  will settle down to constant values in the long run,  $\hat{N}_{i+1}$  will continue to fluctuate, according to (12), in response to fluctuations in  $\hat{Q}_{i+1}$ . As a result, the slope of the relative price line  $b_i^1/e_{i+1}$  will fluctuate as  $\hat{Q}_{i+1}$  moves. Specifically, when  $b_i^1$  is low,  $\hat{Q}_{i+1}$  will fall below its long-run average

<sup>13</sup>Assuming that  $b_1 - v_1$  is a constant amounts to ignoring the dependence of shading on expected number of bidders. This effect is discussed in fn. 6.

FIGURE 1.  $(Q_t, Q_{t+1})$  INDIFFERENCE CURVES

value, denoted as  $\hat{Q}_A$  in Figure 1,  $e_{t+1}$  will then rise, and  $b_t^1/e_{t+1}$  will become flatter, decreasing  $\hat{Q}_{t+1}$  even more. As  $\hat{Q}_{t+1}$  falls,  $e_{t+1}$  then falls a bit more, further reducing  $\hat{Q}_{t+1}$ , and so on. However, this effect will quickly stabilize because, according to (4), the sensitivity of  $e$  to  $\hat{Q}$  rapidly lessens as  $\hat{Q}$  departs from  $\hat{Q}_A$ .<sup>14</sup> Conversely, when  $b_t^1$  is high and  $\hat{Q}_{t+1}$  is above  $\hat{Q}_A$ ,  $e_{t+1}$  will fall, further increasing  $\hat{Q}_{t+1}$ .

Suppose that the cartel was able to convince the purchaser that the sensitivity of  $e_{t+1}$  to  $\hat{Q}_{t+1}$  was larger than in the competitive auction. Then when a particularly low  $b_t^1$  caused  $\hat{Q}_{t+1}$  to fall, the purchaser's estimate of  $e_{t+1}$  would rise further than the competitive case, forcing  $\hat{Q}_{t+1}$  to fall further than the competitive case at the new tangency, and increasing  $Q_t$ . Figure 1 presents this case, the point  $Q_I$  corresponds to the cartel-induced tangency.  $Q_E$  corresponds to a larger  $Q_t$  than  $Q_C$  does, and hence to excess intertemporal substitution.

Figure 2 depicts the possible competitive and collusive  $e - \hat{Q}$  loci that will generate this result. The collusive locus is significantly steeper around the long-run stochastic equilibrium point  $(\bar{e}, \hat{Q}_A)$  than is the competitive locus.

FIGURE 2. THE RELATIONSHIP BETWEEN  $e$  AND  $\hat{Q}$ 

How might the cartel produce the steeper locus of Figure 2? We suggest two ways. First, the cartel can increase the long-run variance  $\sigma$ . The higher variance means that a given fluctuation in  $\hat{Q}$ , that causes through (12'), a fluctuation in  $\hat{N}$ , will generate a larger fluctuation in  $e$ . The cartel can also use  $\theta$  and  $\hat{N}_A$ , the long-run average number of bidders, to ensure that  $\bar{e}$  still equals  $\bar{b}$ .<sup>15</sup> Second, the cartel can manipulate the number of bidders. Recall that the purchaser does not know the slope in (12') relating  $\hat{N}$  to  $\hat{Q}$ . When this slope is steeper, the sensitivity of short-run entry and exit in the market to  $\hat{Q}$  increases, thus increasing the sensitivity of  $e$  to  $\hat{Q}$ . As an example of this, suppose that the monopoly solution consistent with the competitive  $\hat{Q} - \hat{N}$  slope has  $\sigma = 2$ ,  $\hat{N}_A = 4$ , and  $\theta_1$  chosen so that  $\bar{b} = 2$ . The cartel could then choose  $\theta_1^c$  so that  $\sigma^c = 2$ ,  $\hat{N}_A^c = 6$ , and  $\bar{b}$  again equals 2. Now consider a typical reduction in  $\hat{Q}$ . If  $\hat{N}_A$  falls by 1/2 to 2,  $\hat{N}_A^c$  will fall by 1/2 to 3. But  $(Z_6 - Z_3) > (Z_4 - Z_2)$  where  $Z_i$  is derived from the standard normal power density of Appendix II. Thus the cartel's change in  $e$ ,  $\sigma(Z_6 - Z_3)$ , will

<sup>14</sup> The alternative to this stabilization is a corner solution, which does not contradict our theory, although it is less interesting.

<sup>15</sup> From Appendix II,  $\bar{e} = \sigma Z_N + \theta$ . Neglect shading, when  $N = \hat{N}_A$ , choose  $\theta$  so that  $\sigma Z_{\hat{N}_A} + \theta = \bar{e}$ . The derivative with respect to  $\hat{N}_A$  is  $\sigma(\partial Z_N / \partial \hat{N}_A)$ , which increases linearly with  $\sigma$ .

exceed the competitive locus' induced change,  $\sigma(Z_4 - Z_2)$ .

Note that the cartel manipulates the purchasers estimate of the  $\hat{Q} - \hat{N}$  locus without violating the restrictions of his competitive model of the auction, which is summarized in (12'). As a result of this, the cartel will not reveal its presence. We thus conclude that with proper manipulation of either the variance or the number of bidders, the cartel can alter the long-run relationship between  $e$  and  $\hat{Q}$ , inducing excessive purchaser intertemporal substitution, and earning higher long-run profits than in the standard period-by-period monopoly case.

In summary, we have demonstrated an informational cartel's bidding strategy, and have shown that in the long run, an informational bidders' cartel will outperform more typical cartels on two counts. First, the information cartel will increase profits by increasing purchaser intertemporal substitution of demand; the cartel will accomplish this demand reallocation by manipulating how many of its members bid each period. Second, the cartel will earn these higher profits without ever revealing its presence, because it will not violate the purchaser's competitive structural model of short-run entry and exit in the auction. Specifically, by using its bids to control the purchaser's mean, variance, and pool of bidder estimates, the cartel will escape detection in the long run, while continuing to earn monopoly profits through inflated low bids.

#### E. Stochastically Varying Costs

Our model thus far has assumed the simple stationary cost structure given by equation (1). We conclude our discussion of cartel behavior by pointing out that when the uncertainty in production costs are more complex than this simple case, a wider informational gap can emerge between the bidders' cartel and the purchaser, allowing the cartel to increase profits even further.

As an example, consider the case when  $\bar{p}$  is known to be stochastically rising over time. When the purchaser is uncertain of the trend growth rate in  $\bar{p}$ , the cartel can inflate bids at a faster rate than costs, allowing its profits

to steadily increase. More commonly, however, the purchaser will relate the long-run price increase in the market to some index of economywide inflation, which will impose the constraint:

$$(15) \quad \lim_{t \rightarrow T} \bar{p}_t = a + bt,$$

where  $b$  = inflation rate;  $T$  = purchaser's perception of the long run.

In this situation, should the cartel have some knowledge of  $T$ , it can again increase profits by manipulating the "trajectory" of  $\bar{p}_t$  from the trend  $a + bt$  to a concave form in which prices rise rapidly at first, and then level off.

Finally, consider the situation where  $\sigma_p^2$  fluctuates in addition to  $\bar{p}$ . Here the market will resemble a "classic" rational expectations paradigm in which fluctuations in the low-bid market price must be differentiated into a permanent component, an increase in  $\bar{p}$ , and a transient component, a fluctuation in  $\sigma_p^2$ . We suspect that in this case it will be to the cartel's advantage to fluctuate  $\sigma_p^2$  more than costs dictate, thereby injecting noise into the market. The increase in noise will force the purchaser to attribute more of the fluctuations in market price to transient disturbances, and will therefore induce a higher rate of intertemporal substitution.

#### F. Purchaser Expectations

All of our results thus far have been obtained under the assumption that the purchaser uses a Bayesian mechanism to estimate  $e_t$ . We have been careful to point out that while the bidders' cartel will intentionally misinform the purchaser of the parameters of his structural model, it will whenever possible provide bids that are consistent with this structure. Should the purchaser abandon his Bayesian model of the auction market, the cartel may be discovered and/or lose its freedom to manipulate  $e_t$ .

The Bayesian structure we have presented uses the three variables  $R_t$ ,  $m_t$ , and  $s_t^2$  to estimate  $e_{t+1}$ . This would be the optimal approach if the purchaser faced competitive producers. Since the variables it uses are all "free" instruments under cartel control, they

provide the potential for extracting extraordinary profits from the purchaser. However, suppose that instead of the Bayesian approach, the purchaser uses a simple adaptive mechanism to calculate  $e_{t+1}$ . That is, suppose that, rather than calculating the mean, variance, and number of suppliers in the auction held during period  $t$ , and inserting these numbers into a structural model of next period's auction, suppose the purchaser merely forms a weighted average of past low bids in determining the expected future low bid. Specifically, suppose

$$(16) \quad e_{t+1} = \sum_{i=1}^{\infty} \alpha_i b_{t-i}^1 + \alpha_0 b_t^1.$$

In this case, short-run cartel profits will fall because the only means open to the cartel of manipulating  $e_t$  is the low bid  $b_t^1$ , and, if  $b_t^1$  is raised, the purchasers will substitute away from period  $t$ . Hence, the cartel suffers short-run losses as opposed to the short-run windfall as it attempts to raise  $e_t$ . More importantly, whereas in the rational expectations model the cartel can always exceed the standard period-by-period monopoly, in this case there is some uncertainty whether the cartel can even fully establish itself. The cartel must spend a long period of time convincing the purchaser to increase his expected price to the cartel's profit-maximizing level. Obviously, the longer the cartel has to spend inflating the purchaser expectations, the more likely the cartel is to fail. Thus one clear advantage of the rational expectations model for the cartel is the speed with which it can train the purchaser to treat the cartel price as "normal." We thus conclude that the adaptive expectations model constrains the cartel to approach the market's monopoly price gradually, since  $e_t$  can be raised above its competitive level only slowly. And while the cartel is struggling to attain its monopoly position, various factors may cause its disintegration because its short-run profits are in this case lower than the long-run case.<sup>16</sup>

<sup>16</sup> Clearly, extending our argument implies that when costs are more complicated than our simple stationary model, adaptive expectations will be even more of an improvement over the complete structural model.

### III. Some Empirical Observations

The most striking implications of our model of collusive behavior is that auction market cartels will actively pass misinformation to relatively uninformed purchasers. We have shown that, as long as purchasers use a rational expectations model to form price expectations, cartels will find it in their interest to manipulate more than simply the level of the low bid. We have identified three separate strategic variables through which a cartel can pass misinformation to a purchaser and hence manipulate the purchaser's estimate of the low bid. The three variables are 1) the mean of the bids submitted by cartel members; 2) the variance of the bids submitted by cartel members; and 3) the number of long-run market suppliers.

To empirically test the proposition that cartels do more than raise low bids requires a multiperiod auction market in which we can contrast competitive and collusive bidding patterns, and in which the prevalence of collusion was undetected for a significant period of time.<sup>17</sup> An example of a discovered cartel that meets these criteria is in highway construction. There has recently been an unprecedented level of federal antitrust activity in this sector. Between 1977 and 1982, the U.S. Department of Justice filed more than 200 indictments against highway contractors on charges of collusion. Prior to this period, however, antitrust activity in the industry had been rather quiescent and what activity there had been was quite geographically concentrated.<sup>18</sup>

We note that the informational strategies enumerated above will be operative primarily in the short run, but that the highway

<sup>17</sup> In a market where collusion is thought improbable, the assumption that purchasers use a rational expectations model of price formation is fully consistent with the assumption that purchasers choose an efficient mechanism for forming price expectations.

<sup>18</sup> Specifically, from 1955 to 1964 there was only one filing by the Antitrust Division for bid rigging in highway construction, and the defendants in this case were acquitted. In 1972 there was a single successful filing in Illinois and in 1974 there were seven such filings against firms in Illinois. It was not until very late in the 1970's and early in the 1980's that filings in the industry became numerous and widespread.

construction industry has had a sufficiently inflationary cost pattern that the five years we are studying may be considered to be a succession of short runs. In addition, since in highway construction the cartel does not control all projects, collusive firms are continually having to convince the highway department, by using the available informational strategies, that their bids are "reasonable" and that costs have, in fact, taken a once and for all jump.

The purchasers of highway construction are generally government agencies and hence detailed records of each auction are available. In addition, according to interviews with convicted cartel members, the highway bidders cartels that were discovered have not contained all producers, nor have the cartels controlled all bids submitted by members.<sup>19</sup> Hence, our sample contains both collusive and noncollusive bids, and we should be able to contrast cartel-controlled bid situations with competitive ones to determine if the cartel tried to manipulate the purchaser's perceptions of the costs of highway construction in accordance with the predictions of Theorem 1.<sup>20</sup>

Because of data availability we restrict our empirical analysis to the state of North Carolina.<sup>21</sup> In order to assure the plausibility of our assumption that the purchaser (in this case NC DOT) did not consider collusion a major problem, we further restricted the sample to projects put out to bid before 1980 and hence before most of the indictments were filed in North Carolina. Nevertheless, the sample generated by these restrictions is quite adequate since it contains about 1200

highway contracts and 25 colluding contractors.

The North Carolina Department of Transportation (NC DOT) classified each of the contracts in the sample as either collusive or competitive on the basis of conversations with apprehended colluders. Approximately 45 percent of the contracts were labeled collusive by NC DOT. In order to analyze the data we have constructed the indicator variable *COLLUDE* to represent this classification, where *COLLUDE* is 1 if the bids on the project reflected collusion and 0 otherwise.<sup>22</sup> It is important to note that because the classification is based exclusively on conversations with bid riggers, our measure of collusion is completely independent of the actual investigative process by which the officials in North Carolina actually discovered the cartel in the state.<sup>23</sup> This is a point that assumes some significance once we begin to analyze the relationship between this measure of collusion and the actual strategic variables developed below.

To assess the extent to which highway cartels in North Carolina adopted the strategies implied by our model, we first had to develop empirical measures of these strategies. The first two strategies (misinforming the purchaser as to the mean and variance of bids) relate to the bids submitted on a particular contract.<sup>24</sup> However, before the bids collected by NC DOT can be used to test our model, they must be modified.

<sup>22</sup> Despite NC DOT's claim that it has apprehended and questioned all colluders, *COLLUDE* may still reflect some erroneous classifications. Such errors tend to bias our analysis against finding significant differences in the patterns of collusive vs. competitive bid situations.

<sup>23</sup> According to Senior Deputy Attorney General Smith of North Carolina, in a personal communication, "essentially all labeling of NC highway contracts as collusive was based on conversations with bid riggers; essentially no contracts were labeled using investigative tools."

<sup>24</sup> We ignore the distinction between the bids and valuations in our empirical analysis. While we have assumed that we receive a random sample of bids that consequently reflect a random sample of valuations, the relationship between bids and valuations depends on the number of bidders anticipated. Since the anticipated number of bidders is unobserved, we cannot easily transform bids into valuations.

<sup>19</sup> Interviews with convicted cartel members in North Carolina yielded data both on cartel membership and on which contracts the cartel tried to rig. Interestingly enough, cartel members do not always win rigged contracts since there is some entry on specific projects.

<sup>20</sup> Since the cartel does not contain all potential producers, the cartels' bid patterns will also aim to distort the information of noncartel members.

<sup>21</sup> North Carolina provided us with computer readable data describing all highway contracts let in the state during the period 1975–81. The North Carolina data contains a project identifier, each bidder and his bid, the North Carolina Department of Transportation engineer's estimate of the project's worth, and assorted project characteristics.

The bids in this data set represent highway construction projects that vary widely in size, from \$10,000 to several million dollars. The predictions of the theory, of course, refer to bids on a similar size project. In order to handle this problem, we simply normalized the bids in the NC DOT data set by dividing each bid by the state engineer's estimate of the project's worth.<sup>25</sup> Of course, since the engineer's estimate is an estimate of how much the project should cost, dividing it into the bids, especially the low bid, does provide an indicator (at least in this short run) of how enhanced profits are on a specific project. Moreover, since the normalization in part reflects the profit level on the contract and profit levels vary systematically with the business cycle, this normalization is likely to be subject to cyclical variation.<sup>26</sup> This would appear to be a particularly bothersome phenomenon in our case, since the construction industry is notoriously cyclical. To correct for this second problem we have regressed the normalized low bid against a measure of unemployment in highway construction.<sup>27</sup> We have used this regression to adjust not

just the low bid, but all the bids; we denote these residuals as  $RESB_i^l$ .

The residual  $RESB_i^l$  is for the low bid and is likely (at least in the short run) to be a good indicator of cartel activity, that is, a good indicator of enhanced profits. The mean of the  $RESB_i^l$  is denoted  $\overline{RESB}$  and the variance is denoted  $CVBID$ .<sup>28</sup>

The third strategy requires cartel members to choose a bidding pattern that will skew the purchaser's estimate of the number of long-run market suppliers,  $R_t$ . While in most cases not all bidders for a job are cartel members, the cartel can control when its members bid, and how often they bid together. To understand how this might be used to manipulate the purchaser's sense of the magnitude of  $R_t$ , we present a simple recapture model that reflects how the purchaser might use bid patterns to estimate  $R_t$ .<sup>29</sup> Suppose the purchaser has no knowledge of  $R_t$ . He holds an auction and receives  $N_t$  bids. In the next period he holds an auction and receives  $N_{t+1}$  bids where  $K_{t+1}$  of the bids come from firms that also bid in period  $t$ . A naive estimate<sup>30</sup> of  $R_{t+2}$  would be  $N_t + N_{t+1} - K_{t+1}$ ; an estimate that suggests that in order to reduce the purchaser's estimate of  $R_{t+2}$  the cartel will want to choose  $N_t$  and  $N_{t+1}$  small, and  $K_{t+1}$  relatively large. For a variety of reasons, the cartel may not want to choose  $N$  too small;

<sup>25</sup> This method of normalization may bias the data against the effects we expect to find since the engineer's estimate may tend to be inflated on collusive jobs, lowering the value of the normalized bids. If there is any systematic difference between the types of jobs that are colluded upon and the rest of highway construction, then the engineer's estimate for the collusive type of jobs will eventually incorporate collusive profit levels. This is, of course, the objective the cartel is trying to achieve by manipulating the information the purchaser receives.

<sup>26</sup> There are two reasons why a cartel would respond to cyclical variations. First, it needs to make its behavior look like competitive bidding. Second, the behavior of (potential) noncartel bidders forces it to adapt its behavior to the state of the general construction market.

<sup>27</sup> The measure of unemployment is the number employed monthly in construction in a state divided by the ratio of annual average employed in that state's construction sector to one minus the annual employment rate. We have carried this regression out on a national data set of highway contracts in our research on the deterrent effects of antitrust enforcement. In this national regression we determined a single slope common to all states, but separate intercepts for each state. Specifically for North Carolina, this regression yields the regression  $RESB_i^l = b_1/e_t - (.775 + .138CYCLE)$ .

<sup>28</sup> These calculations include data on noncartel member bids for projects where the cartel attempted to rig the auction. While simple, this treatment may mask the difference between truly competitive and collusive bid situations where large numbers of noncartel members bid. This further weakens the  $\overline{RESB}$  and  $CVBID$  correspondence between  $m_t$  and  $s_t^2$  the mean and variance of the valuations. The name  $CVBID$  was chosen because the use of the ratio of the bids to the engineer's estimate is similar to calculating a coefficient of variation.

<sup>29</sup> For a discussion of recapture models, see Norman Johnson and Samuel Kotz (1970, ch. 6).

<sup>30</sup> This estimate is a lower bound on  $R_{t+2}$  if we assume no firms exit between  $t$  and  $t+2$ . A better estimator of  $R_{t+2}$ , assuming the bidding process is like sampling from a hypergeometric distribution, is  $((N_t + 1)(N_{t+1}) / (K_{t+1} - 1))$ . The variance of this estimator depends inversely on  $N$ .

thus we will focus on constructing a measure of  $K_i$ .<sup>31</sup>

For each contractor we have constructed an index  $H(i)$  reflecting how frequently a particular contractor bids with a certain select group of other contractors, as opposed to bidding with a wide variety of other contractors. This index for contractor  $i$ ,  $H(i)$ , is defined as the ratio of the number of different contractors  $i$  had bid with over the period to the number of bidders, other than  $i$ , who have also bid on projects that contractor  $i$  has bid on.<sup>32</sup>

To construct a comparable index for each contract, rather than each contractor, we take the average of the indices for the contractors bidding on a project, and denote this contract index as  $GROUP$ .<sup>33</sup> Contracts for which the  $GROUP$  variable is large correspond to small value of  $K_i$  in the estimator of  $R_i$  we presented above. Thus, if the cartel strategy entails misleading the purchaser about  $R_i$ ,  $GROUP$  should be significantly different for collusive and competitive contracts.

In the first column of Table 1 we present a set of bivariate regressions that relate  $COLLUDE$  (independent variable) to the empirical measures associated with the three cartel informational strategies outlined in Theorem 1. None of the intercepts are reported for the sake of brevity. The results are

TABLE 1—BIVARIATE REGRESSIONS BETWEEN INDICATORS OF CARTEL STRATEGY AND INDICATORS OF COLLUSION

<sup>a</sup>The coefficients divided by estimated standard errors are shown in parentheses.

remarkable support for our model of cartel behavior. Every coefficient is signed according to the predication of our theory and is statistically significant. The mean ( $\overline{RESB}$ ) of submitted bids are higher on bids labeled collusive,<sup>34</sup> the variance of the bids (*CVBID*) are less on collusive bids and the frequency with which bidders on a project have bid together (measured by the relative smallness of *GROUP*) is greater for collusive than noncollusive bids.<sup>35</sup>

<sup>31</sup>First, there are institutional reasons why  $N_i$  cannot be made small. Many states require a minimum number of bidders for projects of various sizes. Second,  $N_i$  plays a role in modifying the purchaser's estimate of future low bids since it determines the weight which the  $i$ th bids' mean and variance receive in updating prior information. For North Carolina, collusive bids have an average  $N$  of about 4 and noncollusive bid situations average about 4.5.

<sup>32</sup>As an example of the construction of  $H(i)$ , suppose two contracts are let, and contractors  $A$ ,  $B$ ,  $C$ , and  $D$  bid on the first contract, and contractors  $A$ ,  $B$ ,  $C$ , and  $E$  bid on the second; then  $H(A) = 4/6$ .

<sup>33</sup>If cartels form among those firms capable of highly specialized work, such as tunnels, we would expect those firms to be bidding together regularly even if they were bidding competitively. Organizing a cartel among a small number of well-known competitors should be relatively inexpensive and so may provide a second rationale for this indicator of collusion. We will discuss a partial test of this proposition later.

<sup>34</sup>It is interesting to note that the results relating  $\overline{RESB}$  to collusion do not simply reflect the effect of  $RESB^1$ , the low bid, on the mean of the bids ( $\overline{RESB}$ ). The results relating  $COLLUDE$  and  $\overline{RESB}$  are essentially the same when the low bid is omitted from the calculation of  $\overline{RESB}$ . Another indicator of the independent manipulation of  $\overline{RESB}$  by the cartel is the relationship between  $\overline{RESB}$  and  $RESB^1$  in this sample. The bivariate regression between  $\overline{RESB}$  and  $RESB^1$  is  $\overline{RESB} = .118 + .460 RESB^1$  (21.5), where the number in parentheses is the coefficient divided by its estimated standard error. Since the average number of bidders on a collusive contract in North Carolina is four, we would expect a coefficient on  $RESB^1$  of approximately .25 if it was only the low bid that was moving the mean.

<sup>35</sup>The two potential "flies in the ointment" here are: 1) the possibility that what we are observing is not the influence of collusion on strategic variables, ( $\overline{RESB}$ ,

In the second column of Table 1 we repeat the same bivariate regression with an alternative indicator of collusion. Here we classify the bids as collusive or noncollusive, not on the basis of whether they have been labeled as such by NC DOT, but rather by the magnitude of  $RESB^1$ . As we noted above,  $RESB^1$  is an indicator in the short run of the degree of profit enhancement embedded in the low bid. The variable  $INDRES$  represents the classification of projects by the size of  $RESB^1$ . The variable  $INDRES$  is 1 if the value of  $RESB^1$  is positive and zero otherwise.<sup>36</sup> While this indicator of collusion is just that, an indicator, and not an actual identification of collusive contracts, it is useful. One potential problem with the variable  $COLLUDE$  is that it undoubtedly involves some misclassifications, especially omissions

of contracts that were rigged but were not identified as such. The variable  $INDRES$  is unlikely to have the same classification bias. Moreover, the use of  $INDRES$  eliminates any possibility that the strategic variable  $GROUP$  is also the variable that generates the classification.<sup>37</sup> As is apparent from the results in Table 1, using  $INDRES$  as an indicator of collusion does not alter the results at all. All signs are as expected and all coefficients are significant.<sup>38</sup>

Another and perhaps somewhat more powerful approach to testing our model of cartel behavior is to consider how well our indicators of strategy jointly predict collusion. If our model is correct, then the probability that a contract is collusive should increase in the mean of the bids ( $\overline{RESB}$ ) and decrease in both the variables  $CVBID$  and  $GROUP$ . A direct test of the power of our model when all three strategies are considered simultaneously is presented in Table 2. We include  $RESB^1$  in this logit estimation basically as a control to see if the other strategic variables have independent predictive power. Again, the result of this empirical test conforms reasonably well to the predictions of our model.<sup>39</sup> When considered

$CVBID$ , and  $GROUP$ ), but rather the mechanism by which the collusive contracts in the sample were identified; or 2) that  $\overline{RESB}$ ,  $CVBID$ , and  $GROUP$  are simply proxies for the cost of collusion. If the collusive contracts were identified by the level of bids, or by the variability of bids, or by the degree to which contractors bid together, we might be observing the classification scheme instead of the impact of cartels on the levels of these variables. The fact that the collusion projects were actually identified by conversations with convicted bidders and not investigative techniques makes this much more a potential than actual problem in all but the case of  $GROUP$  and even here the possibility is quite remote (see fn. 37). On the second point that  $\overline{RESB}$ ,  $CVBID$ , and  $GROUP$  are reflections of the cost of collusion and not necessarily evidence of informational strategies being used by the cartel, we note that our empirical results are basically unaltered when we control for type of contract. If some types of contracts are more easily colluded upon because they represent a recurring and quite standard type of project, then perhaps measures such as  $CVBID$  and  $GROUP$  are simply indicators of the ease of collusion. The invariance, however, of our empirical results to type of project, at least as recorded by NC DOT, suggests that this is not the case.

<sup>36</sup>Because in the short run the purchaser's expectations haven't been fully "inflated" and  $RESB^1$  is a collusive bid,  $RESB^1$  will, in the short run, be positive for the cartel. Moreover, since in our sample not all contracts are collusive,  $e_i$  will reflect both collusive and noncollusive information and  $RESB^1$  will tend to be positive for collusive contracts and negative for competitive contracts. The latter is the case simply because the purchaser's estimate  $e_i$  is contaminated by the cartel's misinformation and hence a competitive bid will generally come in under the estimate.

<sup>37</sup>While  $GROUP$  was not used by NC DOT to identify bid-rigging, it might be acting as proxy for the convicted bid-riggers' memory in naming collusive contracts. The use of  $INDRES$  eliminates the possibility that the correlation between collusion and  $GROUP$  results from the classification process.

<sup>38</sup>It is interesting to note that the magnitude of the coefficients on  $CVBID$ , perhaps the most intriguing of the informational variables, is almost identical in both regressions.

<sup>39</sup>It is surprising that there is enough independent variation in the  $RESB^1_i$  and  $\overline{RESB}$  to support separate, statistically significant coefficients for both variables. This may reflect the fact that even rigged auctions are not entirely under the control of the cartel since they cannot keep noncartel members from bidding, and occasionally winning contracts. We have explored the issue of whether some of our indicators of collusive bidding are merely proxies for the type of project. We found similar results when we restricted the sample to particular types of jobs, such as those involving primarily resurfacing of existing highways. Similar results obtain if, rather than using  $COLLUDE$ , we classify contracts as collusive if they are won by a firm indicted for collusion.  $\overline{RESB}$  is insignificant in the multivariate model.

TABLE 2—MULTIVARIATE LOGIT RESULTS<sup>a</sup>

Independent Variables	Dependent Variable <i>COLLUDE</i>
<i>RESB</i> <sup>1</sup>	1.99 (2.27)
<i>RESB</i>	3.46 (3.18)
<i>CVBID</i>	-53.9 (-5.83)
<i>GROUP</i>	-22.0 (-13.5)

<sup>a</sup>The estimated asymptotic standard errors divided into the coefficients are shown in parentheses.

jointly, the three indicators of strategy *RESB*, *CVBID*, and *GROUP* are all related to the possibility of collusion in the manner suggested by our model and, more significantly, they show up as independent indicators of collusion even where we control for what is perhaps the best indicator of cartel activity in the short run, *RESB*<sup>1</sup>.

As noted above, in the short run, the cartel is in the process of manipulating the purchaser's expectations and its low bid will be above the purchaser's estimate of the project's cost. Moreover, since our sample contains both collusive and competitive contracts, the low bids on competitive contracts will tend to be below the purchaser's estimate of costs. This will be the case because while the purchaser's estimate is contaminated by data from collusive contracts, the bid itself in competitive contracts is simply a reflection of underlying costs. Hence, as we've noted previously, the magnitude of *RESB*<sup>1</sup> itself can be used in the short run as an indicator of the likelihood of collusion on a specific contract.

To the extent that the magnitude of *RESB*<sup>1</sup> is an indicator of collusion, our model suggests that it, like the direct indicator of collusion, *COLLUDE*, ought to be predictable from the value of *RESB*, *CVBID*, and *GROUP*. A test of our assertion concerning the predictability of *RESB*<sup>1</sup> is provided in Table 3. The results again are remarkably consistent with the implications of our theory. Moreover, since the dependent variable here is the magnitude of the low bid (*RESB*<sup>1</sup>)

and not whether the contract was identified as collusive, the results cannot simply reflect the fact that variables such as *RESB*, *CVBID*, or *GROUP* were used to identify collusion in the sample.

Overall, the empirical tests on the North Carolina data provide substantial support for our model. Cartels in practice appear to do more than simply raise the low bid on specific projects; they appear to be actively engaged in misinforming purchasers.

#### IV. Conclusion

In this paper we have investigated the impact of asymmetric information on the character and extent of collusion in multiperiod auction markets. Our analysis suggests that cartels will be especially pernicious in markets where information transmittal is potentially important. In such markets, cartels are likely to seriously impede if not entirely block the flow of accurate information through the market. Cartels in these cases appropriate the returns to superior information, and they do this not by disseminating the information, but rather by suppressing it. Cartels restrict not only the supply of traditional commodities, but also the flow of accurate information.

The passing of misinformation to the purchasers would appear, from our analysis, to be an extremely important aspect of cartel behavior, especially cartels operating in auc-

tion markets. In this regard, it is quite significant that we are actually able to observe this behavior in what is one of the most collusion-prone industries, road building. The empirical evidence that we have been able to assemble on bid-rigging in North Carolina road building indicates that cartels do in fact attempt to misinform purchasers. The evidence here indicates that cartels do more than simply raise the minimum bids on the specific projects.

The specific problem we chose for detailed analysis in this paper is a very common one. Essentially, we examined the problem of how a purchaser evaluates whether any specific offer represents a "good buy." While we study this problem in the context of an auction, the reader, we assume, will appreciate the generality of this concern. Judging whether a particular offer is a good buy or, in our case, whether a low bid is attractive, will be important to a purchaser whenever the prices facing him have an important stochastic component and whenever he has significant possibilities for intertemporal substitution.

#### APPENDIX I

Here we derive the Bayesian estimate of the expected future low bid,  $e_{t+1}$ . Let  $g_t$  denote the best subjective approximation to the true cost density  $f$  prior to period  $t$ 's auction. Following Fisher (see George Box and George Tiao, 1973), the equation relating  $g_t$  to the best approximation to  $f$  subsequent to period  $t$ 's auction,  $g_{t+1}$ , may be written

$$(A1) \quad g_{t+1}(x) = \lambda(\bar{p}, \sigma_p^2 | \text{data}) g_t(x).$$

Under competitive conditions the bids  $b_i^t$  form a Nash noncooperative equilibrium in the auction market such that no individual bidder has any incentive to deviate from his bid  $b_i^t$  when all other bidders follow their Nash strategies and bid  $b_j^t$ ,  $j \neq i$ . In general, the bids  $b_i^t$  are a function of both the number of bidders in the market,  $N_t$ , and the true valuations  $v_i^t$ . Given  $N_t$ ,  $b_i^t$  is known to be a strictly increasing, and hence invertible func-

tion of the valuation  $v_i^t$ .<sup>40</sup> furthermore, the function relating  $v_i^t$  to  $b_i^t$  can be explicitly calculated. Therefore, when the period  $t$  bids  $b_i^t$  are submitted, the period  $t$  valuations  $v_i^t$  can be exactly determined.

Armed with the bidders valuations  $v_i^t$  and the knowledge that the density  $f$  is normal, the update equation (A1) is particularly simple:<sup>41</sup>  $g_t$  should be chosen normal in each period; and, if  $g_t$  is distributed normal  $N(\theta_t, \sigma_t^2)$ , then  $g_{t+1}$  is distributed normal  $N(\theta_{t+1}, \sigma_{t+1}^2)$ , with

$$(A2) \quad \theta_{t+1} = (w_t \theta_t + N_t m_t) / (w_t + N_t)$$

$$\sigma_{t+1}^2 = \frac{w_t \sigma_t^2}{w_t + N_t} + \frac{w_t N_t (m_t - \theta_t)^2}{(w_t + N_t)^2} + \frac{N_t s_t^2}{w_t + N_t},$$

where  $w_t = w_{t-1} + N_{t-1}$ ,  $N_t$  = number of bidders in period  $t$ .

To estimate the expected low bid in period  $t+1$ , the revised density  $g_{t+1}$  is combined with the estimate of the expected number of bidders in period  $t+1$ ,  $\hat{N}_{t+1}$ , which is given by equation (4). The density of the expected low-bid valuation  $b_t^1$  is then

$$(A3) \quad \text{low}(x) = \hat{N}_{t+1} (1 - G_{t+1}(x))^{\hat{N}_{t+1}-1} g_{t+1}(x).$$

Finally, the expected low bid in period  $t+1$  is then simply the expectation of (A3) corrected for the distinction between the low valuation, and the Nash low bid:

$$(A4) \quad e_{t+1} = b(\hat{N}_{t+1}, \int_0^\infty x \hat{N}_{t+1} (1 - G_{t+1}(x))^{\hat{N}_{t+1}-1} g_{t+1}(x) dx).$$

<sup>40</sup> See, for example, Plott.

<sup>41</sup> For an exposition of this result see Box and Tiao (ch. 1).

## APPENDIX II

Here we prove Theorem 1:

- (a)  $\partial e_t / \partial R_t < 0$ ; (b)  $\partial e_t / \partial m_t > 0$ ;  
(c)  $\partial e_t / \partial s_t^2 < 0$ .

## PROOF:

In this proof we always assume that  $R_t$ ,  $m_t$ , and  $s_t^2$  may be chosen completely independently of one another, meaning that we consider the effects of any one of these three variables on the other two to be 0.

From (2),

$$e_t = b \{ \hat{N}_{t+1}, \bar{low}(\hat{N}_{t+1}, m_t, s_t^2) \}$$

where  $\bar{low}$

$$= \int_0^\infty x \hat{N}_{t+1} \{1 - G_{t+1}(x)\}^{\hat{N}_{t+1}-1} g_{t+1}(x) dx.$$

Thus

$$\begin{aligned} de_t = & \left( b_1 + b_2 \frac{\partial \bar{low}}{\partial \hat{N}_{t+1}} \right) \frac{\partial \hat{N}_{t+1}}{\partial \hat{R}_{t+1}} \frac{\partial \hat{R}_{t+1}}{\partial R_t} dR_t \\ & + b_2 \frac{\partial \bar{low}}{\partial \theta_{t+1}} d\theta_{t+1} + b_2 \frac{\partial \bar{low}}{\partial \sigma_{t+1}^2} d\sigma_{t+1}^2. \end{aligned}$$

From Appendix I and equations (3) and (4):

$$\frac{\partial \hat{R}_{t+1} \partial \hat{N}_{t+1}}{\partial R_t \partial \hat{R}_{t+1}} > 0;$$

$$d\theta_{t+1} = \frac{N_t}{w_t + N_t} dm_t > 0 \text{ for positive } dm_t$$

$$d\sigma_{t+1}^2 = \frac{N_t}{w_t + N_t}$$

$$\left( \frac{2w_t(m_t - \theta_t)dm_t}{w_t + N_t} + ds_t^2 \right) < 0$$

$$\text{for } ds_t^2 < \frac{-2w_t(m_t - \theta_t)dm_t}{w_t + N_t}.$$

From footnote 6 it follows directly that  $b_1 < 0$ ,  $b_2 > 0$ . Thus, we need only show that  $\partial \bar{low} / \partial \hat{N}_{t+1} < 0$ ,  $\partial \bar{low} / \partial \theta_{t+1} > 0$ , and  $\partial \bar{low} / \partial \sigma_{t+1}^2 < 0$ , and the results will follow.

Consider the standard normal density  $\phi(x) \sim N(0, 1)$ , and its associated cumulative distribution function  $\Phi(x)$ . Let  $Z_N = E\{\min(x_1, \dots, x_N)\}$  where the  $x_i \sim$  identically and independently distributed  $\phi(x)$ . Now consider  $g(x) \sim N(\theta_{t+1}, \sigma_{t+1}^2)$  and cumulative distribution function  $G_{t+1}(x)$ . Set

$$\bar{low} = E\{\min(y_1, \dots, y_N)\},$$

where  $y_i \sim$  identically and independently distributed  $g(x)$ . Then

$$\bar{low} = \int_{-\infty}^{\infty} x N g(x) [1 - G(x)]^{N-1} dx.$$

Now define  $\hat{x} = (x - \theta_{t+1}) / \sigma_{t+1}$ . Then

$$dx = \sigma_{t+1} d\hat{x}, \quad g(x) = \phi\left(\frac{x - \theta_{t+1}}{\sigma_{t+1}}\right) / \sigma_{t+1},$$

$$G(x) = \Phi\left\{(x - \theta_{t+1}) / \sigma_{t+1}\right\},$$

$$\text{and } xg(x) = [\hat{x}\sigma_{t+1} + \theta_{t+1}]\phi(\hat{x}) \frac{1}{\sigma_{t+1}}.$$

Substituting yields

$$\begin{aligned} \bar{low} &= N \int_{-\infty}^{\infty} \sigma_{t+1} \hat{x} \phi(\hat{x}) [1 - \Phi(x)]^{N-1} d\hat{x} \\ &\quad + \theta_{t+1} N \int_{-\infty}^{\infty} \phi_1(\hat{x}) [1 - \Phi(\hat{x})]^{N-1} d\hat{x} \\ &= \sigma_{t+1} Z_N + \theta_{t+1}. \end{aligned}$$

Using the well-known result (see Maurice Kendall and Alan Stuart, 1968, ch. 14) that  $Z_1 = Z_N < 0$  for all  $N > 1$ , and  $Z_N < Z_{N-1}$  for all  $N$ , it follows directly that

$$\frac{\partial \bar{low}}{\partial \hat{N}_{t+1}} < 0; \quad \frac{\partial \bar{low}}{\partial \theta_{t+1}} > 0; \quad \frac{\partial \bar{low}}{\partial \sigma_{t+1}^2} < 0.$$

(Note that  $\partial \bar{low} / \partial \sigma_{t+1}^2 < 0$  requires  $m_t > \theta_t$ , which follows from  $\partial \bar{low} / \partial \theta_{t+1} > 0$ .)

# Unemployment Duration and Incidence: 1968–82

By HAL SIDER\*

Cyclical changes in unemployment are a predominant feature of the labor market. Between 1973 and 1975, and again between 1979 and 1982, unemployment rates in the United States increased by roughly 70 percent. The labor market has further witnessed a large secular increase in unemployment over recent years. Between business cycle peak years 1969 and 1979, for example, unemployment rates increased by 65 percent. Such fluctuations and trends necessarily depend on the flows of workers into and out of unemployment. This paper examines the extent to which cyclical and long-term variations in aggregate unemployment reflect changes in the incidence of new spells and changes in average spell duration for those out of work.

A central issue in the analysis is the estimation of the length of completed unemployment spells from data on spells yet in progress. The construction and interpretation of such statistics has been at the heart of much recent debate on the dynamics of unemployment.<sup>1</sup> Previous duration estimates generally have been based on the assumption that unemployment reflects steady-state conditions; that is, that flows into and out of unemployment are constant over time. This

assumption is inappropriate for the analysis of cyclical fluctuations and long-term trends.

The paper first examines methodological issues in deriving estimates of the incidence and duration of completed unemployment spells. A modeling framework is developed and implemented based on aggregate probabilities that individuals continue in unemployment from one month to the next. The procedure does not rely on the restrictive steady-state assumption. The data that underlie construction of U.S. unemployment statistics for January 1967 through December 1982 are applied to the nonsteady-state model and are reapplied in the steady-state setting. Comparison of the estimates derived from these models indicates that calculations based on the steady-state framework systematically underestimate duration during recessions and overestimate duration at cyclical peaks. The paper then focuses on nonsteady-state measures of duration and incidence to explain fluctuations and trends in total unemployment. The results indicate that changes in duration play a very important role in explaining these phenomena.

## I. Measuring Unemployment Duration and Incidence

For many years, the Bureau of Labor Statistics has reported the average length of unemployment spells in progress. This measure, however, provides little direct evidence about the fully realized length of unemployment spells. Conceptually, the average duration of a completed spell can be determined by tracing an entering cohort through their unemployment experience.<sup>2</sup> The size of an entering cohort is denoted  $f(0)$  and the vector  $f(x)$ ,  $0 < x < n$ , represents the number of

I also thank Joe Antos, Arlene Holen, Michael Horrigan, Richard McDonald, George Neumann, John Raisian, Andy Sparks and the referees for their comments and assistance. Any errors, of course, are my responsibility. The research reported here was undertaken while I was at the U.S. Department of Labor. The views expressed are my own and do not necessarily represent the position or policies of the U.S. Department of Labor, or the U.S. Commission on Civil Rights.

<sup>1</sup>George Akerlof and Brian Main (1980, p. 885), for example, ask whether unemployment is better described in terms of stocks of people unemployed for long periods of time, or rather in terms of flows of persons whose spells of unemployment are quite short.

<sup>2</sup>See John Carlson and Michael Horrigan (1983) for a clear discussion of various duration measures and problems in interpreting these statistics.

individuals remaining in unemployment after each of  $x$  periods, where  $n$  is the maximum number of periods in unemployment. The average duration of a completed spell is simply the sum of these spells weighted by their completed length divided by the number of individuals that make up the cohort. In discrete terms, this can be written

$$(1) \quad S = \sum_{x=1}^n \frac{x(f(x-1) - f(x))}{f(0)} \\ = \sum_{x=0}^n \frac{f(x)}{f(0)}.$$

The process can be restated equivalently in terms of the probabilities of continuing in unemployment from one period to the next where  $p_x = f(x)/f(x-1)$ :

$$(2) \quad S = (1 - p_1) + 2p_1(1 - p_2) \\ + 3p_1p_2(1 - p_3) + \dots \\ = 1 + p_1 + p_1p_2 + p_1p_2p_3 + \dots,$$

or, more generally,

$$(3) \quad S = \sum_{x=1}^n g(x) \left[ \prod_{j=0}^{x-1} p_j \right] (1 - p_x),$$

where  $p_0$  is the probability of being in the initial cohort (and equals unity). The product of the  $p_j$ 's and  $(1 - p_x)$  is the share of the original cohort that exits unemployment after  $x$  periods. The function  $g(x)$  weights exiting individuals by the length of their completed spell. (In (2),  $g(x) = x$ ; although, as described below, this function can take a more general form.) Derivation of (3) does not require an assumption of steady-state conditions. Evaluation of (3) using current continuation rates yields an estimate of the expected spell duration for a synthetic cohort of individuals entering unemployment. It reflects the average completed spell duration that would be incurred if current continuation rates were maintained into the future. A variant of (3) based on this concept is estimated below.

The level of unemployment observed at any time depends on past and present values of  $f(0)$ , the size of entering cohorts, and past and present values for the vector of continuation rates. It is important to note, however, that if  $f(0)$  individuals enter unemployment each period and continuation probabilities are constant over time (i.e., the economy is in a steady state), then total unemployment at any point in time can be expressed:

$$(4) \quad U = f(0) + p_1f(0) + p_1p_2f(0) + \dots,$$

and

$$(5) \quad U = S \cdot f(0).$$

That is, under steady-state conditions, unemployment can be expressed as the product of incidence and average completed spell duration.

Implementation of nonsteady-state duration measures (such as (3)) requires estimates of continuation probabilities which can be derived only by observing the behavior of individuals or a cohort over time. However, if it can be assumed that unemployment reflects steady-state conditions, cross-section data on spells in progress can be applied to the problem of estimating completed durations.<sup>3</sup> In a steady state, the number of people leaving unemployment is equal to the number entering unemployment at any time and the duration distribution of spells in progress is constant. In such an equilibrium, differences in the observed number of in-progress spells of successive weeks duration reveal the probability that a member of the cohort remains unemployed an additional week. If steady-state conditions hold, mean completed spell duration can be calculated:

$$(6) \quad S' = \sum_{x=0}^n \frac{f(x, t)}{f(0, t)},$$

where  $f(x, t)$  denotes the number of individuals unemployed for  $x$  periods duration at

<sup>3</sup>This result was first discussed by Hyman Kaits (1970), who provides an excellent intuitive and algebraic derivation of the steady-state model.

time  $t$ . In a steady state, the number of individuals unemployed for  $x$  periods is constant so,  $f(x, t) = f(x)$  for all  $x, t$  and  $S' = S$ .

If steady-state conditions do not hold, then estimates based on this assumption will be biased. If unemployment is rising, then  $f(0, t) > f(0)$  and  $S' < S$ . In this situation, a cross-section distribution of in-progress spells by weeks duration is weighted too heavily by newer (and shorter) spells. The implicit continuation probabilities underestimate the true ones, resulting in underestimates of completed spell lengths.<sup>4</sup> When business conditions are improving, the cross-section distribution is weighted excessively by longer spells which results in overestimates of mean completed spell length. Thus, estimates based on inappropriate steady-state assumptions dampen actual fluctuations in duration over the business cycle.

Other authors have focused on the average completed spell length for the currently unemployed, as opposed to average duration for an entering cohort (George Akerlof and Brian Main, 1981). The completed spell length for this group is comprised of current plus remaining duration. Under steady-state conditions, persons are interviewed, on average, halfway through their unemployment spell, so simply doubling the average duration of spells in progress reveals the mean completed length of these spells. When steady-state conditions do not hold, however, the "doubling" estimator can be biased. The cyclical pattern of the bias is similar to that described above. In a recession, continuation

rates are rising and expected remaining duration on average exceeds the average current duration. A complementary bias is introduced when business conditions are improving.

Finally, steady-state methods can also bias estimates of the incidence of new spells. In a recession, the product of current incidence and mean completed duration exceeds the current level of unemployment because the newer, larger entering cohorts have not yet had time to filter through the entire duration schedule ( $U < S \cdot f(0, t)$ ). If average completed spell duration is known, steady-state estimates of incidence ( $I'$ ) calculated as the ratio of total unemployment to average completed duration (from (5)) will be biased downward in recessions ( $I' = (U/S) < f(0, t)$ ). The bias is reversed during periods of economic expansion. In this way, steady-state techniques may also dampen cyclical fluctuations in incidence. In practice, however, as discussed above, steady-state duration estimates can be biased which in turn can introduce an offsetting error in incidence estimates. In a recession, for example,  $S' < S$  so  $(U/S') > (U/S) < f(0, t)$ . The resulting cyclical nature of the bias in incidence estimates is ambiguous.

A large majority of attempts to analyze aggregate trends in unemployment duration and incidence have relied on steady-state techniques. These estimates have often been derived by fitting a smooth curve—often the *gamma* density—to average annual data on the number of spells in progress of various durations. The shape of this curve yields an implicit set of continuation rates for groups of individuals unemployed different lengths of time. The parameters of this function yield estimates of mean completed spell duration. This methodology, which essentially approximates equation (6), was developed by Hyman Kaitz (1970) and formalized by Stephen Salant (1977). Akerlof and Main (1980) applied these techniques to develop estimates of mean completed spell duration estimates for U.S. unemployment for 1948–78. Others, including Kim Clark and Lawrence Summers (1979) have implemented duration estimates based on continuation rates derived from longitudinal data (the gross-flows figures from the *Current*

<sup>4</sup>Consider the very simple example in which two individuals enter unemployment each period and the probability of remaining unemployed an additional weeks is .5. In equilibrium (weeks  $t, t+1$ ), a cross section of different cohorts yields continuation rates identical to those derived by tracing a cohort over time. If the size of an entering cohort increases, however, calculations based on a cross section of cohorts underestimate the true (constant) continuation rate and thus underestimate duration.

Duration	Number Unemployed		
	week $t$	$t+1$	$t+2$
1	2	2	3
2	1	1	1

Population Survey) and have thus avoided the steady-state assumption.<sup>5</sup> However, the data that form the basis of these estimates are generally not available in a time-series long enough to permit evaluation of secular and cyclical trends.<sup>6</sup>

## II. Data and Model Specification

Experiments with alternative methods for estimating the duration and incidence of unemployment spells are based on the monthly unemployment estimates of the Bureau of Labor Statistics.<sup>7</sup> Aggregate unemployment totals classified by reported weeks of spell duration (covering weeks 0–99) from January 1967 through December 1982 are utilized. These data reflect weighted counts from the *Current Population Survey (CPS)*. These schedules also serve as the basis of published unemployment duration schedules, which are reported in terms of intervals (less than 5 weeks, 5–10, 11–14, 15–26, 27+).<sup>8</sup>

The full schedule of in-progress spells is dominated by a pattern of spikes that reflect response bias among individuals in the sample. Local modes occur at durations corresponding roughly to monthly, quarterly,

half-yearly, and yearly points in the schedule. Few people, for example, report spells of five weeks duration relative to the number who report spells of four or six weeks. This pattern must be accounted for (and smoothed) in deriving either steady-state or nonsteady-state measures of completed spell duration. Consistent with this pattern of response bias, recent studies by James Poterba and Summers (1983) and by Norman Bowers and Francis Horvath (1985) reveal frequent errors in reported labor force status, unemployment duration and reasons for unemployment in the *CPS*. These insights are gleaned from the *CPS* reinterview surveys and matched longitudinal files on individuals who, due to the rotation group structure of the *CPS*, continue in the sample in consecutive months. The authors conclude that these problems may severely limit the reliability of econometric analyses focusing on matched longitudinal files. However, the offsetting nature of many reporting errors and the stability of rotation group bias tends to mitigate (though not eliminate) the impact of such errors on aggregate data, such as those utilized below.<sup>9</sup>

Problems and irregularities in the data have made the estimation of completed spell duration nearly as much an art as a science. Due to problems in fitting a smooth curve to the irregular weekly duration schedule, Kaiz and many subsequent analysts have utilized the

<sup>5</sup>Nicholas Kiefer, Shelly Lundberg, and George Neumann (1983) find that estimates of the duration distribution of completed unemployment spells derived from this type of data are sensitive to the assumed functional form. Although estimates of mean duration are fairly robust, alternative forms yield differing estimates of tail probabilities.

<sup>6</sup>An exception is J. K. Bowers and D. Harkess (1979) who estimated expected completed spell durations that rely on less-restrictive assumptions for biannual data from the British unemployment register for 1963–73. Norman Bowers (1980) has used the gross-flows data from the *CPS* to develop steady-state estimates of expected completed spell duration for 1969–79.

<sup>7</sup>Unemployment is defined to include individuals who are not working but have actively searched for a job in the past four weeks. The *CPS* questions on duration refer to the number of weeks since the onset of an individual's current (uninterrupted) spell. Unemployment spells can end with either employment or departure from the labor force.

<sup>8</sup>Implementation of these intervals in duration models incorporates the fact that, due to rounding procedures, reported intervals (< 5, 5–10, ...) reflect actual intervals (0–4.5, 4.5–10.5, ...). Alternative interval schedules outlined below also account for rounding rules.

<sup>9</sup>Both Poterba-Summers and Bowers-Horvath show that individuals in the *CPS* sample in consecutive months who report unemployment in both months tend to overstate increases in duration. This bias can affect the magnitude of duration estimates but does not necessarily affect cyclical duration patterns. For example, individuals classified as new entrants or reentrants to unemployment appear to overstate duration more than those classified as job losers and job leavers. However, the share of total unemployment made up by entrants and reentrants declines during recessions, a pattern that works counter to observed cyclical fluctuations in duration. Analysis of reinterview surveys by Poterba-Summers and Alfred Tella (1976) indicate that unemployment tends to be underreported as unemployed individuals are often classified as out of the labor force. Tella also finds more underreporting during recessions. The cyclical effect of such underreporting on duration estimates, however, is unclear as the location of such individuals in the duration schedule is not known.

published duration interval data as the basis of their estimates. The implementation of the nonsteady-state model (equation (3)) is also based on an interval representation of the underlying data, but the intervals are re-defined to correspond roughly to integer multiples of the monthly sampling window (0–4 weeks, 5–8, 9–12, 13–26, 27–39, 40–52, 53–75, 76–99).

With such an interval selection, a set of continuation rates can be derived by comparing adjacent interval populations in consecutive months. These continuation rates, in turn, are used to evaluate duration. For example,  $p_{1t}$  (the probability in month  $t$  of an individual continuing from his first to second month of unemployment) is calculated simply as the number of people in their second month of unemployment (at time  $t$ ) as a proportion of the number of individuals in their initial month of unemployment in month  $t-1$ :  $p_{1t} = h(1, t)/h(0, t-1)$ .<sup>10</sup> The aggregate probability of continuing in unemployment from the second to third month, and from the third to fourth month, etc., is calculated in a similar fashion. In this manner, a full set of continuation rates that exhaust the duration schedule can be derived for each month in the sample.<sup>11</sup>

Implementation of equation (3) further requires specification of  $g(x)$ , the function that weights individuals leaving unemployment by the appropriate completed duration. If spells

end, on average, halfway through the month then  $g(1)$  would equal .5;  $g(2)$  would equal 1.5; etc. Actually, the average departure date is somewhat before midmonth because as the month progresses, fewer members of the original group remain and the absolute size of the outflow declines. Specification of  $g(x)$  relies on the assumption that the probability of exit for individuals remaining unemployed is constant over the course of a month.<sup>12</sup>

Intervals selected as integer multiples of the sampling window have the property that the transition weeks in the schedule (weeks 4, 8, 12, etc.) generally correspond to spikes in the data. The published intervals fully incorporate transition weeks with adjoining intervals of shorter duration. This is not completely appropriate because spikes at transition weeks likely include individuals who underreport as well as some who overreport true duration. Accounting for this problem requires an algorithm to allocate transition points between adjacent intervals. The simple rule used below is to allocate these weeks equally across adjacent intervals.

Estimates of completed spell duration are evaluated using current continuation rates and weights,  $(p_{x,t}, g(x, t))$ . The resulting measure reflects the expected completed spell duration of a synthetic cohort that enters unemployment and faces current economic conditions throughout their unemployment spell. In this sense, the expected duration statistic permits estimation of long-run responses to steady-state changes in the macroeconomic climate.<sup>13</sup>

The assumptions required for construction of this statistic are less restrictive than those

<sup>10</sup> This contrasts with the implicit steady-state estimate:  $p_{1t} = h(1, t)/h(0, t)$ .

<sup>11</sup> More specifically, continuation probabilities are calculated through the following transitions:

< 5 weeks in month  $t-1$  to 05–08 weeks in  $t$   
 05–08 weeks in month  $t-1$  to 09–12 weeks in  $t$   
 09–12 weeks in month  $t-1$  to 13–16 weeks in  $t$   
 13–26 weeks in month  $t-3$  to 27–39 weeks in  $t$   
 27–39 weeks in month  $t-3$  to 40–52 weeks in  $t$   
 40–52 weeks in month  $t-3$  to 53–65 weeks in  $t$   
 53–75 weeks in month  $t-6$  to 76–99 weeks in  $t$   
 76–99 weeks in month  $t-6$  to 100+ weeks in  $t$

The 100+ category is defined as one-half of the total reporting 99 weeks, the truncation point in the data. These intervals more fully characterize the long-durations tail of the distribution of in-progress spells (relative to the BLS schedule) and slightly reparameterize shorter durations. Longer intervals at longer durations are necessary to smooth spikes in the data at 26, 52, 75, and 99 weeks.

<sup>12</sup> A similar point has been noted by James Luckett (1979). Assuming constant exit rates from each cohort within a month; one-half of eventual exits over the month have left when  $g(x) = \ln((1 + p_x)/2)/\ln(p_x)$ .

<sup>13</sup> Because calculation of long-duration continuation rates requires lags of more than one month, estimates of expected spell duration will tend to lag slightly current conditions. The bias, however, is likely to be relatively small due to the small share of spells that reach long durations and the relative stability of continuation rates at long durations. Expected duration measures have also been implemented by Clark and Summers (1979), Bowers and Harkess, and Bowers.

for the steady-state model, but are important nevertheless. More specifically, it is necessary to assume that steady-state conditions hold over the sampling interval. That is, it is necessary to assume that entrants to unemployment arrive at a constant rate and face constant exit probabilities throughout the interval period. This assumption, however, allows estimation of weekly inflows into unemployment. Specifically, the number of individuals observed with less than five weeks unemployment at time  $t$ ,  $h(0, t)$ , can be considered as the result of a renewal process that reflects a weekly continuation rate  $p_1^*$  (derived from the estimated monthly continuation rate for individuals in their first month of unemployment,  $p_1$ ) and the number of individuals,  $N$ , that entered unemployment each week over the course of the month. Assuming four weeks per month:

$$(7) \quad h(0, t) = N(1 + p_1^* + p_1^{*2} + p_1^{*3}).$$

This expression can be solved for  $N$ , yielding an estimate of the average weekly incidence of unemployment for each month of the sample.<sup>14</sup>

### III. Comparison of Alternative Estimates of Duration and Incidence

This section compares steady-state and nonsteady-state estimates of the completed duration and incidence of unemployment spells derived from aggregate unemployment data. First, steady-state duration estimates are derived using data defined in a manner that conforms with the nonsteady-state model; next, biases in steady-state measures are examined by comparing these estimates with nonsteady-state results.

The first step in the evaluation process is to examine the sensitivity of published steady-state results to changes in the parameterization of the duration intervals. The basic framework of Salant is reproduced utilizing a

nonlinear least squares algorithm to estimate the parameters of the *gamma* density from average annual data on in-progress spells. First, the results of Akerlof and Main, that were based on standard published duration intervals, are reestimated. The reproduced results (not reported) are very similar to those reported by the authors except for 1973, for which the recalculated spell duration is 71 percent of the original and for 1976, for which the model fails to converge.<sup>15</sup> For other years, recalculated mean durations average 98.5 percent of those reported by Akerlof and Main. The steady-state results are also robust with respect to respecification of the duration intervals. Reestimation on this basis results in mean completed spell durations that are, on average, 1.5 percent shorter than those derived using the published schedule.<sup>16</sup>

Allocating transition weeks between adjacent intervals, however, has a substantial impact on duration estimates. Because these transition weeks are no longer grouped with weeks of shorter duration, the revised distribution is less compressed toward shorter durations. This yields higher continuation rates and longer average durations. Allocating transition points equally between adjacent periods increases mean duration by an average of 34.1 percent. This change affects the levels but not cyclical patterns in the steady-state estimates. The simple correlation between annual measures of spell duration based on alternative treatments of transition weeks exceeds .99.

Before presenting the nonsteady-state estimates of expected completed spell durations, the set of continuation probabilities that underlie these estimates is examined (Table 1). The estimates reveal the oft-noted pattern that the aggregate probability of remaining

<sup>15</sup>The results of the analysis of the sensitivity of steady-state duration estimates are available on request from the author.

<sup>16</sup>This difference is attributable to the reparameterization of the shorter intervals, not the more detailed specification of the long-durations tail. Results based on a more detailed specification of the tail and standard shorter intervals are identical (to the tenth of a month) to the base results.

<sup>14</sup>A similar point is noted by George Perry (1972). Estimation of  $N$  is based on the average of 4.3 weeks per month.

TABLE 1—AGGREGATE MONTHLY PROBABILITIES  
OF CONTINUING IN UNEMPLOYMENT  
(Nonsteady-State Estimates)

Month of Unemployment	1969	1975	1979	1982

19-24	.90	.97	.92	.97

Note: Calculations described in text.

unemployed increases with duration. Continuation rates fall a bit at longer durations, a pattern that may reflect an increased likelihood of withdrawal from the labor force for

the very long-term unemployed. Continuation rates also follow a distinct cyclical pattern, rising during recessions (in 1975 and 1982, for example). This cyclical pattern is observed for each duration-specific group.

Annual means of completed spell durations estimated by steady-state and nonsteady-state methods are presented in Table 2. The reported estimates are based on identical interval specifications and treatment of transition points in the underlying data. The results show that nonsteady-state measures are, in general, slightly higher than steady-state estimates and that the magnitude of the difference is related to business cycle conditions. More specifically, the largest wedge between steady-state and nonsteady-state measures is observed in years of deteriorating business conditions (1970, 1975, 1982).

<sup>a</sup>Derived from nonlinear least squares estimates of *gamma* density based on intervals (0-4, 5-8, 13-26, 27-39, 53-75, 76-99, 100+).

<sup>b</sup>Estimates of equation (3) based on same intervals.

<sup>c</sup>Derived from equation (5) using steady-state duration estimates.

<sup>d</sup>Derived from equation (7).

<sup>e</sup>Standard deviation divided by mean of series.

<sup>f</sup>Derived from regression of log of annual unemployment measures on *IPI*\* (deviations from trend in log of the Industrial Production Index). Standard errors are shown in parentheses.

This is consistent with the discussion in Section I.

As a result, the steady-state measure ( $S'$ ) exhibits considerably less variability over time than the nonsteady-state estimate ( $S$ ). For example, the coefficient of variation for the annual nonsteady-state model is .26 compared to .19 for the steady-state result. The magnitude of the bias introduced by steady-state techniques can be summarized in regressions of the log of annual duration measures on a trend term and business cycle indicator  $IPI^*$ , that is constructed as deviations from trend growth in the log of the Industrial Production Index. The results (also reported in Table 2) indicate that a 1 percent decline in  $IPI^*$  increases the nonsteady-state measure by 3.2 percent. The corresponding increase in  $S'$  is 1.9 percent. The difference between the estimates is significantly related to business cycle conditions.<sup>17</sup>

Despite the cyclical nature of the bias, in years of improving business conditions, the steady-state estimates do not exceed the nonsteady-state measure. One reason for this is related to the secular growth in unemployment that has resulted from increased growth in the labor force and apparent trend increases in the "full-employment" unemployment rate.<sup>18</sup> Steady-state methods are biased downward by trend growth in unemployment because the cross-section distribution is weighted too heavily by the newer and thus shorter spells. This growth accounts for a sizeable share of the "cyclically adjusted"

difference between steady-state and nonsteady-state measures.<sup>19</sup>

Table 2 also presents steady-state and nonsteady-state estimates of the incidence of new unemployment spells. The steady-state incidence measure is defined using the equality in (5) and the steady-state duration measure; the nonsteady-state incidence measure is estimated from (7). The two series are roughly similar in magnitude and variability. The steady-state measure is larger by an average of 5 percent and the nonsteady-state measure is somewhat more variable, although both measures are less variable than the duration statistics. Regressions of the log of annual incidence estimates on  $IPI^*$  and a linear trend indicate that a 1 percent decrease in  $IPI^*$  increases the steady-state measure by .4 percent and the nonsteady-state measure by .6 percent. The difference between the incidence measures is again significantly related to  $IPI^*$  indicating that steady-state methods dampen estimates of cyclical fluctuations in incidence.

#### IV. Trends in Unemployment Duration and Incidence

Analysis of secular and cyclical fluctuations in unemployment requires analysis of variation in its components. This section examines in a bit more detail secular and cyclical changes in unemployment based on the nonsteady-state measures of incidence and duration derived above. Trends in incidence and duration are described first; the long-run impact of business conditions on unemployment is then analyzed and the share of such fluctuations attributable to incidence and duration is examined.

Various unemployment indicators for 1968–82 are summarized in Table 3. Unem-

<sup>17</sup>A similar cyclical bias is observed in estimates of completed spell duration for the currently unemployed. The steady-state measure is calculated as twice average current duration of in-progress spells. A nonsteady-state counterpart can be calculated by adding the average current duration of in-progress spells to an estimate of expected remaining duration. The latter measure is constructed by evaluating an expected duration equation (similar in concept to equation (3)) for each cohort of the currently unemployed and then taking a weighted average of this measure over all cohorts. A 1 percent decline in  $IPI^*$  increases the "doubling" statistic by 1.4 percent and the nonsteady-state measure by 1.9 percent. The difference in these measures is significantly related to  $IPI^*$ .

<sup>18</sup>See Joseph Antos, Wesley Mellow, and Jack Triplet (1979) for a discussion and review.

<sup>19</sup>Business cycle "peak-to-peak" average monthly unemployment increased by roughly 8 percent annually between 1969 and 1979. Experiments with mean continuation rates were performed to simulate the size of various cohorts under this level of unemployment growth. Steady-state estimates based on the simulated data underestimate the true duration—which is constant by assumption—by about 3 percent, although this figure is somewhat sensitive to the assumed timing of the increase over the course of a year.

TABLE 3—UNEMPLOYMENT INDICATORS: 1968–82

	Unemployment Rate (1)	Average Unemployment (2)	Expected Completed Spell Duration (3)	Expected Completed Spell Duration for Currently Unemployed (4)	Weekly Inflow (5)	Incidence Rate (6)	<i>IPI</i> * (7)
1968	3.6	2822	6.1	18.2	433	.55	.005
1969	3.5	2835	6.2	17.4	440	.54	.022
1970	4.9	4092	8.2	20.1	555	.67	-.036
1971	5.9	4996	9.8	25.1	549	.65	-.046
1972	5.6	4843	8.7	25.0	554	.64	.015
1973	4.8	4306	7.3	20.6	559	.63	.069
1974	5.5	5078	8.4	21.3	653	.71	.039
1975	8.4	7827	14.6	32.7	684	.73	-.081
1976	7.6	7289	11.3	32.4	660	.69	-.007
1977	6.9	6857	9.6	28.3	689	.70	.024

ployment and unemployment rates increased substantially over the period. This long-term increase is attributable as much to lengthened spell durations as to the increased incidence of unemployment spells. Between peak business cycle years 1969 and 1979, for example, average unemployment increased about 110 percent while the incidence of unemployment spells increased by only 64 percent.<sup>20</sup> The average unemployment rate increased 63 percent over these years while the incidence rate (calculated as the ratio of weekly incidence to average monthly labor force) grew by just 26 percent. The expected duration of unemployment spells increased by 34 percent over this period.

Cyclical changes in unemployment are composed of fluctuations in incidence and

average spell duration. Changes in duration, in turn, depend on variability in the underlying sets of continuation rates. A series of experiments is performed (similar to those reported in Table 2 for analyzing the cyclical bias in steady-state methods) in which the log of the continuation rates estimated for each month in the sample are regressed on a distributed lag of *IPI*\*, a time trend, and month-specific dummy variables.<sup>21</sup> The results indicate that continuation rates are more cyclically sensitive at shorter durations (see

<sup>20</sup>As a basis for comparison, average monthly initial claims for unemployment compensation increased by 94 percent between 1969 and 1979.

<sup>21</sup>The incidence model incorporates a 3-month distributed lag of *IPI*\*; the duration model a 6-month lag; and the unemployment and unemployment rate models are based on a 12-month lag. Lag lengths were selected by testing restrictions on models incorporating longer lags. Similar models were estimated by Clark and Summers (1981) to explain employment variability. Estimation included a correction for first-order serial correlation. Similar models were estimated utilizing BEA's index of coincident indicators to measure business cycle conditions and yielded very similar results.

TABLE 4—VARIABILITY IN UNEMPLOYMENT MEASURES, JANUARY 1968–DECEMBER 1982

	Mean	Coefficients of Variation		Regression Coefficients <sup>a</sup>

<sup>a</sup> From regressions of log dependent variables on distributed lag of  $IPI^*$  (deviations from trend in the log of the Industrial Production Index), time and month-specific dummy variables. Standard errors are shown in parentheses. Elasticities reflect the sum of distributed lag coefficients.  $N=180$ .

<sup>b</sup> Shown in weeks.

<sup>c</sup> Shown in thousands.

<sup>d</sup> Percentage of labor force.

Table 4). A 10 percent decline in  $IPI^*$  increases continuation rates by 8 to 9 percent for individuals in their first six months of unemployment, about 5 percent for individuals in their second six months, and 4 percent for individuals in their second year.

Cyclical patterns in expected duration and incidence are also reexamined using monthly data in regressions that include  $IPI^*$ , a trend term, and month-specific dummy variables. Not surprisingly, the results (see Table 4) are very similar to those based on annual data

reported in Table 2. The cyclical elasticity of expected duration shows the equilibrium change in duration that would result from a steady-state change in  $IPI^*$ . The results show a cyclical elasticity of  $-3.2$  for the duration measure and  $-.60$  for incidence. The cyclical elasticity of the incidence rate is estimated to be  $-.69$ .

All measures follow a highly significant positive trend. The coefficient on the trend variable indicates that mean completed spell duration has increased about 3.4 percent per

year, *ceteris paribus*. The incidence rate has increased by roughly 1.8 percent per year while total incidence has increased by about 4.2 percent annually.

Recall that in a steady-state environment, unemployment is the simple product of incidence and mean duration. In turn, the sum of the long-run percentage responses of incidence and duration to business cycle conditions yields the long-run percentage response in total unemployment. The elasticities reported in Table 4 thus imply that a 1 percent (steady-state) decline in  $IPI^*$  yields an equilibrium increase in unemployment of roughly 3.8 percent (3.9 percent in the unemployment rate). In contrast, the sum of the elasticities from the steady-state model (reported in Table 2) indicate that a 1 percent decline in  $IPI^*$  would increase unemployment by only about 2.3 percent.

As a check on these estimates of the long-run effect of business conditions on the components of unemployment, regressions were estimated to examine directly cyclical fluctuations in total unemployment and the unemployment rate. The regressions included a distributed lag of  $IPI^*$ , a linear trend, and month-specific dummy variables. The results indicate an elasticity of the unemployment rate with respect to  $IPI^*$  of 3.0 percent and an elasticity of unemployment with respect to  $IPI^*$  of 2.8 percent. It is likely that these figures are somewhat smaller than the long-run impacts derived from the incidence and duration measures because recessions are generally too short for the larger entering cohorts to filter through the entire duration schedule. As a result, new (higher) steady-state unemployment levels are not achieved. The expected duration measure, recall, simulates an instantaneous adjustment to new economic conditions.

Of the resulting equilibrium response of unemployment to business conditions, fully 84 percent (3.2/3.8) results from changes in duration. The rest results from cyclical fluctuations in incidence. By means of contrast, the steady-state results reported by Perry attribute a more important role for changes in incidence for the years 1954 through 1971. For prime-age males, for

example, Perry attributes roughly 55 percent of changes in unemployment to changes in incidence. For females, the corresponding figure is roughly 60 percent.

In sum, the incidence and mean completed duration of unemployment spells are cyclical in nature. However, fluctuations in unemployment appear to result more from changes in spell duration and less from the changes in the incidence of new spells. The use of steady-state methods to derive such estimates dampens cyclical responses and understates the influence of duration on changes in unemployment.

## V. Conclusions and Qualifications

This paper examines cyclical changes in unemployment. These fluctuations can be described in terms of changes in the incidence and average duration of unemployment spells. As such, a primary focus of the paper is the development of unbiased measures of the incidence and duration of such events.

A new method for estimating mean completed spell length is developed and the results are compared with those based on the fairly restrictive assumption that unemployment reflects steady-state conditions. The observed biases introduced by steady-state techniques are consistent with those expected. Analysis of nonsteady-state measures indicates that duration and incidence are quite cyclical and that changes in duration play a predominant role in explaining both cyclical fluctuations and secular trends in unemployment.

These results are subject to some important qualifications. First, the underlying data do not permit distinguishing between spells which end due to (i) employment and (ii) departure from the labor force. Spells are not differentiated by reason for unemployment (entrant, layoff, job leaver, etc.). Estimates pertain to single spells as opposed to average unemployment experience (which may include multiple spells). Finally, the data reveal distinct patterns of response bias which necessitates the use of somewhat *ad hoc* smoothing techniques. The results, however,

seem fairly robust with respect to the choice of smoothing algorithm.

Despite these limitations, the estimates reveal some intriguing patterns in the composition of fluctuations and trends in aggregate unemployment, as officially defined. The determinants of large and significant positive trends in incidence and duration remain important and unanswered policy questions.

# The Advantages of Being First

By A. GLAZER\*

In analyzing issues of entry into a market, different economists have chosen to emphasize different aspects of the issues. Some look at the advantages, such as economies of scale, learning by doing, or strategic opportunities, that early entrants possess over later ones (see for example, Avinash Dixit, 1979, 1980; B. Curtis Eaton and Richard Lipsey, 1979; Richard Schmalensee, 1982; and A. Michael Spence, 1979, 1981).

Other economists suppose that in equilibrium a firm should gain no advantage from entering before others. Richard Jensen (1982) uses this assumption to analyze the diffusion rate of an innovation among firms that learn over time and that have different prior beliefs about the innovation's profitability. Jennifer Reinganum (1981) describes the Nash equilibrium timing of entry in a world consisting of identical firms, but in which entry at different times entails different costs. J. Luis Guasch and Andrew Weiss (1980) examine the effect of uncertainty about workers' qualifications on the entry decisions of firms, and Takeo Nakao (1980) looks at entry under conditions of oligopoly.

Entry, however, should not be studied in isolation from failure. Alvin Star and Michael Massel (1981), for example, find that out of 17,252 retail establishments established in Illinois during the 1960's, only 33.2 percent survived after five years. J. Hugh Davidson (1976) finds that about 70 percent of test market brands were not expanded nationally, and could therefore be considered failures. Any model of entry into an industry must allow for the possibility of failure, and Boyan Jovanovic (1982) and Steven Lippman and R. P. Rumelt (1982) indeed do so. They, however, give little attention to the sequential process of firm entry.

We thus find two differing streams of thought: one that emphasizes the advantages of early entry, and one that focuses on the condition that firms earn identical profits. Integrating these views is a primary purpose of the theoretical part of this paper. The paper also complements the aforementioned studies by considering the possibilities of both entry and failure, and by treating market conditions as a random walk, which allows for a deeper analysis of the characteristics of innovation. The assumptions of the model are the topic of Section II, Section III describes the equilibrium entry times of firms, and Section IV explains why the failure rates of first and later entrants may be similar, and offers some results of relevance to government policy promoting innovation. It is most important, however, to first examine some empirical evidence concerning whether or not first entrants enjoy special advantages.

## I. Some Data

Several investigators find that the most successful existing firms are those that devoted the most resources to research and development, or that innovated the earliest (see Edwin Mansfield, 1962; Ira Whitten 1979). But the sample of existing firms is a biased one. It consists of *successful* innovators; little record is left of those innovators who failed. It could well be that in successful markets first entrants perform exceedingly well, but that any firm contemplating entry could do as well by entering an established market as by developing a new one in which the risk of collapse is high. Indeed, R. G. Cooper (1979), who studies 100 new product successes and failures, finds that being first in a market offered no particular advantage. William Dillon et al. (1979) reach a similar conclusion in their investigation of 109 firms that had introduced new products.

These studies, interesting though they are, rely on analyses of questionnaires sent to

\*School of Social Sciences, University of California, Irvine, CA 92717. I am grateful to an anonymous referee for helpful comments.

managers. It would be useful to examine the actual behavior of firms. Unfortunately, requisite data for most industries are not available, and a study must therefore be limited to an industry for which data can be found on the dates of entry and exit of all firms, including firms which failed soon after they were established. Perhaps the best such information is available for newspapers. In particular, *A Bibliography of Iowa Newspapers, 1836-1976* (see Alan Schroder, 1979) lists all daily newspapers published in that state; it also lists changes in the name of a newspaper, the date at which a newspaper began publication, and the date (if any) at which the newspaper merged with some other newspaper. These data thus permit a careful study of entry and exit in several dozen markets.

The first question I investigate using these data is whether first entrants in successful markets do possess some advantage over second entrants. In eighteen of the markets studied, a first and second entrant existed simultaneously for some length of time; presumably these were in some sense successful markets, markets attractive enough to attract at least two firms. Following the second entrant's appearance, the first entrant survived longer than did the second entrant in thirteen of these markets; such a skewed distribution could occur by chance with a probability of less than 5 percent. It appears that in a competition between first and second entrants, the first entrant possesses a significant advantage.

The results differ if one looks at all markets, rather than just at successful ones. In general, first entrants enter a market before second entrants do, and a statistical method must be devised to separate the effects of the date of entry from the order of entry. I therefore constructed a sample of newspapers of which half were first entrants and half were second entrants. To each first entrant in the sample founded in year  $t$ , there corresponds a second entrant (not necessarily in the same city) that was founded within five years of year  $t$ . The distribution of entry dates for first and second entrants studied is therefore similar. In this sample, which includes some markets in which only

one newspaper ever appeared, I found no significant difference between the survival rates of first and second entrants: twenty-five years after founding, first entrants had a survival rate of 32 percent, and second entrants a survival rate of 39 percent. The *chi-square* test for the difference in survival rates for the years 1, 2, 3, ..., 40 is significant at only the 35 percent level. First entrants did not appear to be more successful than later entrants.

In short, in successful markets first entrants did better than second entrants; but when one looks at all markets this superiority disappears. Explaining these results is the topic of the following sections.

## II. Assumptions

To highlight the essential features of the problem, and to make the analysis more tractable, I assume that there are only two potential entrants in the market—entrepreneurs  $A$  and  $B$ . Each of these entrepreneurs can enter the market at any time he wishes; entry entails a nonrecoverable fixed cost of  $F$  dollars. An entrepreneur can also exit the industry whenever he wishes, and he can later reenter the industry after again incurring a cost of  $F$  dollars.

The profits earned by a firm are a function of the firm's costs, of the market demand curve, of whether or not another firm is already established at the time the firm in question enters the market, and of the length of time that it and its competitors have been in business. For simplicity, suppose that the cost function is fixed over time, but that the market demand curve can shift over time. The characteristics of the demand curve can be summarized by the value of a parameter,  $s$ , which can represent, for example, the size of a city in which a product is sold, or the average income level of consumers. The firm's profits are an increasing function of  $s$ , other things held constant.

The value of  $s$  varies over time in a stochastic manner; more specifically, it follows a random walk. Let the passage of time be measured at discrete intervals of length  $\Delta t$ . Over each such interval  $s$  can increase or decrease by the fixed amount  $\Delta s$ . The prob-

ability of such an increase is  $p$ , and the probability of such a decrease is  $1-p$ . The value of  $p$  is constant over time, so that the stochastic process is stationary; that is, the probability that  $s$  takes on some value at time  $t + \Delta t$  depends only on the value of  $s$  at time  $t$ . It will be convenient to allow for growth in the market, which is translated into the assumption that  $p$  is greater than one-half.

The model I use considers discrete values of  $\Delta s$  and  $\Delta t$ . It will occasionally prove useful to examine a model in which the changes are very small and occur in very rapid succession, or where the limits of  $\Delta s$  and  $\Delta t$  are zero. Strictly speaking, the passage to the limit entails the study of diffusion processes. William Feller (1957, pp. 323-27) shows, however, that the equations for a random walk hold when the passage to such a limit is taken.

Suppose that at time zero the market is so small as to make entry then unprofitable. Over time the market is expected to grow, although the date at which  $s$  will attain some particular value is a random variable. In any one market, however, the random walk describing changes in the value of  $s$  will take some unique path, and it is therefore meaningful to speak of the first instant at which  $s$  attains a specified value. Define  $t(s^*)$  as the time to first passage, or the first instant at which  $s = s^*$ ; the value of  $s$  is less than  $s^*$  prior to time  $t(s^*)$ , and its value may be less than, equal to, or greater than  $s^*$  after time  $t(s^*)$ . Two possible paths for a random walk are shown in Figure 1 by the lines  $OA$  and  $OB$ . When the random walk takes path  $OA$ ,  $t(1)$  equals 1; when the path is  $OB$ ,  $t(1)$  equals 9.

Most generally, each firm's profits will depend not only on the state of the market, but also on the length of time it has been in business. We might expect a first entrant's profits following the entry of a second firm to be higher the longer the first firm was the sole one in the industry; the opposite relation might hold for the later entrant. Unfortunately, modeling such a general model presents great difficulties. A second firm would enter the market when the value of market demand became greater than some critical

FIGURE 1

value, which value depends on the length of time that has elapsed since the other firm entered the market. Thus, a firm might enter the market when  $s = \bar{s}$  if the other firm was established one year ago, but would not enter when  $s = \bar{s}$  if the other firm was established three years ago.

I simplify matters by considering two possibilities only. The first is that a first entrant enjoys no advantages over a later entrant. The second possibility is that the advantages of early entry are totally independent of the length of time that elapses between the appearances of the first and the second firm.

Under these assumptions the firm's profit rate at time  $t$  depends on the value of  $s$  at that time, and, perhaps, on whether or not another firm preceded it. Given the value of  $s$  at any instant, an entrepreneur can calculate the probability distribution functions of  $s$  for all subsequent instants. The expected value of a firm's future profits, discounted to time  $t$ , is therefore a function only of the value of  $s$  at that time and of the number of competitors then established.

Denote by  $V^k(s)$  the expected value of a firm's future profits, discounted to time  $t(s)$ , given that it is the  $k$ th entrant into the industry; at the time of its entry  $k-1$  firms had already been established and were still in business. Let  $V^{1.5}(s)$  be a firm's expected future profits, discounted to time  $t(s)$ , if both firms simultaneously entered the industry at time  $t(s)$ .

I assume that profits are an increasing function of  $s$ , so that  $V^k(s + \Delta s) - V^k(s) > 0$ .

for all  $\Delta s > 0$ . For given values of  $s$  and of the number of competitors, an early entrant enjoys profits no lower than those enjoyed by later entrants:  $V^k(s)$  is a nonincreasing function of  $k$ .

Note that in calculating  $V^k(s)$  the firm takes into account the possibility that  $s$  may become so low that it would leave the industry. This is especially likely to occur if the firm enters the market at a time when  $s$  is already low. An entrepreneur can also consider the possibility that at some future date another firm will enter the market. In short, the value of  $V^k(s)$  incorporates all factors that affect a firm's profits.

It will prove useful to have a notation for a firm's expected profit during finite periods of time. Let  $\pi^k(s_1, s_2)$  represent the firm's expected profits during the interval  $[t(s_1), t(s_2)]$ , discounted to time  $t(s_1)$ , given that the firm was the  $k$ th entrant into the industry, and that during the interval  $[t(s_1), t(s_2)]$  no new firms entered. Recall that  $t(s)$  is a random variable, and that from the instant at which  $s = s_1$ , until the instant at which  $s = s_2$ , the value of  $s$  is a random variable as well (compare in Figure 1 the paths  $OA$  and  $OB$  which both start at  $t(0) = 0$  but which then follow different paths). Thus, the actual profits earned by the firm during any interval of time is a random variable, although the firm knows the expected value of those profits.

Finally, define  $R(s_1, s_2)$  as the expected discount factor. More specifically, for  $s_2 > s_1$  let  $f(t, s_1, s_2)$  be the probability that  $t(s_2) - t(s_1) = t$ , let  $r$  be the discount rate, and let

$$R(s_1, s_2) \equiv \sum_{t=0}^{\infty} f(t, s_1, s_2)(1+r)^{-t}.$$

### III. Equilibrium Entry Times

The analysis is an interesting one only if there will be at least two entrants which do not enter simultaneously. I shall present some assumptions that ensure these results.

Assume that for some sufficiently high value of  $s$ , say  $\hat{s}$ , the value of  $V^2(\hat{s})$  is greater than  $F$ . A standard result in the theory of random walks among an infinite number of states (E. B. Dynkin and V. A.

Uspenskii, 1963, p. 51) is that if the transition probabilities from  $s$  to  $s + \Delta s$  are all greater than or equal to  $1/2$ , then with probability 1 each state will be reached within a finite number of periods. The second firm will enter when, say,  $s = s^* \geq \hat{s}$ , and under the just-stated conditions this will occur with probability one. The first firm will enter no later than at time  $t(s^*)$ .

Consider next the question of whether entry will occur simultaneously. Define  $t(s_A)$  as firm  $A$ 's entry time, and let firm  $B$  correctly anticipate this entry. Suppose for the moment that firm  $A$  is not the latest entrant. Entrepreneur  $B$ 's problem is then to choose a value of  $s$ , where  $s \geq s_A$ , and thus an instant  $t(s) \geq t(s_A)$ , such that entry at that instant would maximize his profits. Entrepreneur  $B$ 's profits, discounted to time  $t(s_A)$ , are then:

for entry at time  $t(s_A)$ ,

$$V^{1.5}(s_A) - F = \pi^{1.5}(s_A, s) - F \\ + V^{1.5}(s)R(s_A, s);$$

for entry later than at  $t(s_A)$ ,

$$(V^2(s) - F)R(s_A, s).$$

A necessary condition for  $t(s_A)$  to be firm  $B$ 's optimal entry time is that

$$(1) \quad \pi^{1.5}(s_A, s_A + \Delta s) \geq [V^2(s_A + \Delta s) \\ - V^{1.5}(s_A + \Delta s)]R(s_A, s_A + \Delta s) \\ + F[1 - R(s_A, s_A + \Delta s)]$$

for  $\Delta s > 0$ .

Analogously, we can examine the profitability of firm  $B$  entering the industry prior to time  $t(s_A)$ . A necessary condition for  $t(s_A)$  to be firm  $B$ 's optimal time is that

$$(2) \quad \pi^1(s_A - \Delta s, s_A) \leq [V^{1.5}(s_A) - V^1(s_A)] \\ \times R(s_A - \Delta s, s_A) + F[1 - R(s_A - \Delta s, s_A)].$$

To recapitulate, each firm will wish to enter at time  $t(s_A)$  only if doing so maximizes its expected profits given that the other firm

enters then, or, equivalently, only if both inequalities (1) and (2) hold.

Suppose that the functions  $\pi^k$  and  $V^k$  are continuous in  $\Delta s$ , that  $\lim_{\Delta s \rightarrow 0} R(s, s + \Delta s) = 1$ , and that  $\lim_{\Delta s \rightarrow 0} \pi^k(s, s + \Delta s) = \lim_{\Delta s \rightarrow 0} \pi^k(s - \Delta s, s) = 0$ . (What this means is that very small changes in  $s$  occur in arbitrarily short periods of time.)<sup>1</sup>

Consider first the possibility that the advantages of first entry are noninfinitesimal even if the second firm enters immediately after the first. That is,  $[V^{1.5}(s_A) - V^1(s_A)] \neq 0$ , but is instead a negative number. In that case, inequality (2) cannot hold for all  $\Delta s$ , and entry will not occur simultaneously.

Consider next the possibility that there are no advantages to early entry: the value of  $V^2(s_A + \Delta s) - V^{1.5}(s_A + \Delta s)$ , which appears in inequality (1), is zero, and the value of  $V^{1.5}(s_A) - V^1(s_A)$  which appears in equality (2), is also zero. Observe that the value of  $R(s_1, s_2)$  depends only on the value of  $s_2 - s_1$ , and not on the levels of  $s_1$  or  $s_2$ ; thus  $R(s_A, s_A + \Delta s)$  appearing in expression (1) is equal to  $R(s_A - \Delta s, s_A)$  appearing in expression (2).

In this case, simultaneous entry will occur only if  $\lim_{\Delta s \rightarrow 0} \pi^{1.5}(s_A, s_A + \Delta s) \geq \lim_{\Delta s \rightarrow 0} \pi^1(s_A - \Delta s, s_A)$ . Note that, in general,  $\pi^1(s, s + \Delta s) > \pi^{1.5}(s, s + \Delta s)$  because  $\pi^1(\cdot)$  represents expected profits earned by a monopolist during some interval, whereas  $\pi^{1.5}(\cdot)$  represents the profits earned by each duopolist. Let  $\pi^1(s, s + \Delta s) - \pi^{1.5}(s, s + \Delta s)$  equal  $c\Delta s$ , where  $c$  is some nonnegative number. Then simultaneous entry occurs only if  $d\pi/ds > c$ , or only if a firm's profits are affected more by a slight change in market conditions than by the entry of an additional firm. This possibility is not impossible, but appears to be quite unlikely. The result can be summarized as follows.

**PROPOSITION 1:** *Sufficient conditions for nonsimultaneous entry are that either of the*

*following conditions hold:*

- (a)  $V^1(s) - V^{1.5}(s) > 0$ ;
- (b)  $\lim_{\Delta s \rightarrow 0} [\pi^1(s, s + \Delta s) - \pi^{1.5}(s, s + \Delta s)]$   
 $> \lim_{\Delta s \rightarrow 0} [\pi^1(s, s + \Delta s) - \pi^1(s - \Delta s, s)]$ .

I shall henceforth assume that condition (b) holds for all  $s$ . I shall allow for the possibility that (a) does not hold, or that  $V^k(s) = V^j(s)$  for all  $k$  and  $j$ .

**PROPOSITION 2:** *Consider a Nash equilibrium in which each entrepreneur correctly anticipates the entry time of the other firm. In such an equilibrium the two firms earn identical profits.*

**PROOF:**

Consider an equilibrium in which firm  $A$  enters first, at time  $t(s_A)$ . Firm  $B$ , the second entrant, will enter when  $s$  first attains a value  $s^*$ , defined as the lowest value greater than  $s_A$  for which

$$(3) \quad \pi^2(s^*, s^* + \Delta s) \geq FR(s^*, s^* + \Delta s),$$

$$(4) \quad \pi^2(s^* - \Delta s, s^*) \leq FR(s^* - \Delta s, s^*).$$

Firm  $B$ 's expected profits, discounted to time 0, are

$$Z_B(s^*) = [V^2(s^*) - F] R(0, s^*).$$

Firm  $A$ , the first entrant, has expected profits of

$$Z_A(s_A, s^*) = [\pi^1(s_A, s^*) - F] R(0, s_A) \\ + V^1(s^*) R(0, s^*).$$

Suppose first that  $Z_A$  is greater than  $Z_B$ . Then firm  $B$  could increase its profits by adopting the following strategy. Instead of entering when  $s = s^*$ , it enters when  $s = s_A - \Delta s$ , for arbitrarily small  $\Delta s$ . Once such entry occurs, firm  $A$  will enter when  $s = s^*$ . With the continuity of  $\pi(s, s + \Delta s)$ ,

<sup>1</sup>For any meaningful process,  $\lim_{\Delta s \rightarrow 0} [t(s + \Delta s) - t(s)] = 0$ ; otherwise  $t(s_2) - t(s_1)$  would have non-finite values for  $s_2 > s_1$ . This is why  $\lim_{\Delta s \rightarrow 0} \pi^k(s, s + \Delta s) = 0$ .

firm  $B$ 's profits will then be  $\lim_{\Delta s \rightarrow 0} Z_A(s_A - \Delta s, s^*) = Z_A(s_A, s^*)$ , which by assumption are greater than  $Z_B(s^*)$ . Thus, entry by the two firms with the first entrant earning larger profits cannot be an equilibrium.

Consider next a putative equilibrium in which the second entrant earns larger profits; that is,  $Z_B(s^*) > Z_A(s_A, s^*)$ . Then firm  $A$  can increase its profits by entering at time  $s^* - \Delta s$  for arbitrarily small  $\Delta s$ . From inequality (3),  $\pi^2(s^*, s^* + \Delta s) \geq FR(s^*, s^* + \Delta s)$ . Proposition 1 implies that  $\lim_{\Delta s \rightarrow 0} [\pi^1(s^* - \Delta s, s^*) - \pi^2(s^*, s^* + \Delta s)] > 0$  and therefore that  $\pi^1(s^* - \Delta s, s^*) > FR(s^* - \Delta s, s^*)$ . This implies that

$$\begin{aligned} Z_A(s^* - \Delta s, s^*) &> Z_A(s^*, s^*) \\ &\equiv [V^{1.5}(s^*) - F] R(0, s^*) \\ &\geq [V^2(s^*) - F] R(0, s^*) \\ &= Z_B(s^*). \end{aligned}$$

Thus, a situation under which  $Z_A(s_A, s^*)$  is less than  $Z_B(s^*)$  cannot be an equilibrium one. This completes the proof of Proposition 2.

**PROPOSITION 3:** *In equilibrium the first firm will enter the market at a time earlier than that which would maximize its profits in the absence of the threat of entry by another firm.*

**PROOF:**

In discussing Proposition 2, I showed that  $Z_A(s^* - \Delta s, s^*)$  is greater than  $Z_B(s^*)$  for some arbitrarily small  $\Delta s$ . Now for some sufficiently low levels of  $s$ ,  $Z_A(s, s^*)$  is negative. Assuming continuity of  $Z_A(s, s^*)$ , there therefore exists a value of  $s_A < s^* - \Delta s$  such that  $Z_A(s_A, s^*) = Z_B(s^*) < Z_A(s^* - \Delta s, s^*)$ . In equilibrium, firm  $A$  enters when  $s = s_A$ . Were firm  $A$  the only possible entrant, it could earn larger profits by entering at a later time, such as at time  $t(s^* - \Delta s)$ . Proposition 3 is thereby proved.<sup>2</sup>

<sup>2</sup>Reinganum obtained similar results in her model which considers firm adjustment costs rather than changing market conditions. Eaton and Lipsey show

#### IV. The Incentives to Innovate

The previous section showed that during the interval  $[t(s_A), t(s^*)]$  the first entrant enjoys a monopoly. This does not mean, however, that the second entrant will appear immediately after the first one does. Thus, the view (see Morton Kamien and Nancy Schwartz, 1982, p. 124) that perfect competition implies *immediate* imitation is not generally valid. This observation in turn leads to

**PROPOSITION 4:** *An innovator can earn economic profits greater than its competitor even if the latter can costlessly and immediately imitate an innovation once it appears on the market.*

**PROOF:**

Suppose an entrepreneur invents a new product. If all firms knew of this innovation, the entrepreneur would be forced to enter the industry at time  $t(s_A)$ , and earn profits no greater than those earned by the imitator who enters at time  $t(s^*)$ . Given secrecy, however, so that the product is concealed until the actual time of entry, the innovator could delay his entry until time  $s^* - \Delta s$  and earn profits of  $Z_A(s^* - \Delta s, s^*)$  which are greater than the profits of  $Z_B(s_A^*) = Z_A(s_A, s^*)$  that will be earned by the imitator. (Of course, entry when  $s = s^* - \Delta s$  need not be the innovator's optimal entry time.) That is, by inventing a new product and keeping its invention secret until it enters the market, the innovating firm can enter *later* than it would have to under conditions of perfect information, and can thereby earn supra-normal profits.

---

that in a spatial model the existing firm will expand rather than allow new firms to enter the industry; in a market for a homogeneous good as described here, this need not occur. Similarly, Ronald Johnson and Allen Parkman (1983) argue that in a market with room for only one firm, the first entrant will appear at the moment expected future profits become zero. They theorize that the entrant's profits should show an increasing trend over time, and find only weak evidence for that. They do not, however, consider the possibility of firm *failure*, and thus, I believe, give an incomplete test of their hypothesis.

Once the innovation is introduced, other firms can immediately copy it and enter the industry. As seen in the previous section, however, the second firm will not find it profitable to enter immediately, so that the innovating firm will enjoy monopoly profits for some length of time. Clearly the innovator would earn even greater profits if no firm could imitate the product: imitation reduces, and need not eliminate, the innovator's profits.

One would expect that an increase in the profits that a firm can earn would cause entry to occur earlier. This will be true, however, only in special cases.

**PROPOSITION 5:** *Let  $\pi^k(S)$  be a firm's rate of profit during the interval  $(t, t + \Delta t)$  given that  $k$  firms are in the industry and given that  $s = S$  at time  $t$ . An exogenous increase in  $\pi^k(S)$  need not hasten the date of first entry.*

**PROOF:**

Suppose that  $\pi^k(S)$  is exogenously increased for all values of  $s$  greater than  $s^*$ , where  $s^*$  is the value of  $s$  at which the second firm will enter the industry.<sup>3</sup> In the initial equilibrium the first entrant's expected profits, discounted to time zero, are

$$\begin{aligned} Z_A = & Z_B(s^*) + \pi^1(s_A, s^*) R(0, s_A) \\ & - F [R(0, s_A) - R(0, s^*)] \\ & + [V^1(s^*) - V^2(s^*)] R(0, s^*). \end{aligned}$$

The described increase in  $\pi^k(S)$  does increase  $Z_B$ , but it has no effect on  $\pi^1(s_A, s^*)$ , on  $F$ , or on  $R$ .

The effect of such a change on the value of  $V^1(s^*) - V^2(s^*)$  is ambiguous. The increase in  $\pi^k(S)$  for all  $s > s^*$  may increase the advantages of early entry, so that  $V^1(s^*) - V^2(s^*)$  increases. In equilibrium  $Z_A$  must equal  $Z_B(s^*)$ , but with the new value of  $V^1(s^*) - V^2(s^*)$ ,  $Z_A$  would be greater than

$Z_B$ . A new Nash equilibrium would require that firm  $A$  enter earlier than before, thereby reestablishing the equality of  $Z_A$  and  $Z_B(s^*)$ . It should be clear that if  $V^1(s^*) - V^2(s^*)$  decreased, first entry would be delayed; if changes in  $\pi^k(S)$  caused no changes in  $V^1(s^*) - V^2(s^*)$  the timing of entry would also be unchanged. In short, an improvement in expected profitability might delay rather than hasten entry. A similar result holds for changes in  $\pi(S)$  for values of  $s < s^*$ , and for changes in the transition probabilities from one value of  $s$  to another.

Finally, I can solve the puzzle that was a major theme of this paper. Recall that the empirical evidence showed that in markets consisting of two or more firms, the first entrant was more successful than the second. Yet first entrants in general were as likely to fail as second entrants. That is, it appears that first and later entrants earn identical expected profits even though early entrants enjoy strategic or other advantages. My model suggests that competition forces the first entrant to appear at an early stage in the development of a market so that there is a great danger that demand will not increase to the extent predicted. Therefore the market will not reach the necessary critical size in a reasonable time, and the first entrant will fail even before any other firms enter the industry. Later entrants will choose to enter only successful markets which have reached an appreciable size; their problem is the stiff competition given by earlier entrants. Observers who look only at the performance of early entrants in successful markets will overestimate the advantages of innovation.

# Internal Migration and Urban Employment in the Third World

By WILLIAM E. COLE AND RICHARD D. SANDERS\*

For more than a decade Michael Todaro's model has provided a widely accepted theoretical framework for explaining the massive flows of rural urban migration that are observed in many Third World countries.<sup>1</sup> This paper, however, presents data amassed from a wide range of countries to highlight a crucial shortcoming of that model. It will be shown that far from being general in nature, the Todaro approach is limited to explaining the movement of persons possessed of sufficient human capital to qualify them for modern sector employment. Masses of relatively uneducated persons migrate and work in a subsistence world that cannot be explained by the structures of Todaran theory. In turn, the present work utilizes the perspective of the urban subsistence sector to develop a model that serves as a useful complement to that of Todaro.

## I

The burden of the Todaro model was to explain why masses of workers moved from the countryside to the city in the face of sizeable urban pools of unemployed and underemployed. To accomplish this, the model focused attention on the present value of expected earnings rather than current wage rates. Specifically, the rate of rural-urban migration was held to be a function of the difference between the present values of expected urban earnings and expected rural earnings, with the size of the flow of expected urban earnings significantly affected by the probability of obtaining employment

in the urban modern (*U-M*) sector (Todaro, 1979, p. 201).<sup>2</sup>

Even though there might exist an urban pool of underemployed and unemployed labor, a potential migrant would decide to make the cityward trek if the expected *U-M* earnings, properly discounted by the probability factor, exceeded the expected stream of rural earnings. Those migrants not obtaining *U-M* employment in the immediate period are said to accept temporary employment in the urban surplus labor pool (Todaro, 1969, pp. 142 ff.). Although sometimes referring to the surplus labor pool as the traditional sector, the Todaro model clearly assumes that all members of the pool, as well as all migrants, are intent upon eventual *U-M* sector employment.<sup>3</sup> The Todaro model thus explains why there may be more migrants than modern sector job openings and accounts for the growth of the urban pool of surplus labor.

## II. Empirical Evidence

One of the most significant structural changes recently occurring in the Third

<sup>2</sup>Todaro's basic behavioral equation can be shown as

$$V(0) = \int_{t=0}^{\infty} [P(t)Y_u(t) - Y_r(t)] e^{-rt} dt - C(0),$$

where  $V(0)$  is the discounted present value of the net gain from a rural-urban move;  $P(t)$  represents the probability of securing a job in the modern urban sector in period  $t$ ;  $Y_u$ ,  $Y_r$  represent average real income in the modern urban and rural sectors, respectively;  $C$  is the one-time cost of the move; and  $r$  is the migrant's time preference rate of discount. In cases where  $V(0)$  is positive, the economically rational potential migrant will decide to move. All of Todaro's work has assumed that open rural unemployment is nonexistent. A probability of unity is therefore used when calculating expected rural earnings.

<sup>3</sup>This assumption is imbedded in Todaro's treatment of the probability of employment in the *U-M* sector. Other factors constant, that probability varies inversely with the size of the surplus labor pool (see Section III).

\*Department of Economics and Department of Statistics, respectively, University of Tennessee, Knoxville, TN 37916. This paper has benefited from comments by Walter C. Neale and Henry Thompson. The research support of the College of Business Administration is greatly appreciated.

<sup>1</sup>The seminal work of Todaro appeared in 1969 and successive formulations have been faithful to that work.

World has been the rapid growth of an urban subsistence (*U-S*) sector. Elsewhere called the urban informal sector or the urban traditional sector,<sup>4</sup> it comprehends those urban employment categories that feature very low levels of productivity and earnings. The *U-S* sector includes such occupations as domestic service, petty tradesmen (including street vendors), artisans, and the like.

The relative importance of the *U-S* sector can be seen from data reflecting the economic structure of several important cities. It has been estimated that the proportion of Calcutta's urban labor force relegated to the *U-S* sector is 43 percent; for Bogota, 45 percent; and 50 percent in Lagos (Harold Lubell, 1978, p. 753).<sup>5</sup> Census data for Mexico indicate that on the order of 34 percent of the labor force of the huge Federal District may be classified in the *U-S* sector (Secretaría de Industria Y Comercio, 1972). It is widely noted that these sectors exist and are growing in many Third World cities, due in large measure to rural-urban migration.

Two distinguishing characteristics of *U-S* sector employment are very low capital-labor ratios and few if any formal human capital requirements. One therefore finds few if any barriers to entry into *U-S* sector employment. On the other hand, it is widely recognized that *U-M* sector jobs carry education requirements that effectively exclude persons who have acquired little or no formal education. It has been further noted that, for given *U-M* jobs, educational prerequisites tend to escalate as the average level of education rises.<sup>6</sup> (Lisa Peattie, 1968, pp. 137–39; Todaro, 1979, pp. 251 ff.)

<sup>4</sup>Our term "urban subsistence sector" is in large measure synonymous with the widely used term "urban informal sector." Other terms found in the literature are "urban traditional" (Todaro, 1969), "lower circuit" (Milton Santos, 1979), and "protoproletariat" (T. G. McGee, 1971). There are important differences, however, which are explored later when a formal definition of the *U-S* sector is introduced. (See fn. 18 below and the discussion to which it pertains.)

<sup>5</sup>Lubell's terminology is "urban informal sector."

<sup>6</sup>The phenomenon of escalating job prerequisites is sufficiently widespread to have earned the title "credentialism." Jorge Balán et al. noted: "Given a choice provided by an abundant supply of labor,... modern

Mexican census data reveal that the bulk of migration into the Metroplex comes from the most rural and relatively poor states where levels of education are absolutely and relatively low. (Although the present paper treats rural-urban migration in general terms, it utilizes as a reference point, the large urban agglomeration in and around the Federal District of Mexico, which we call the Metroplex.)<sup>7</sup> Surveys confirm that the majority of migrants have minimal educational attainments (Humberto Muñoz et al., 1977, p. 109, and Larissa Lomnitz, 1977, p. 88). There is also evidence that the average education attained by migrants coming into the Metroplex has been falling and that the percentage of migrants originating in strictly rural environs has been growing (Muñoz et al., pp. 106–07), an important distinction between current and earlier migration patterns.

An extensive survey found that over the span of several decades the mean level of education of urban immigrants had regressed toward the rural mean (Harley Browning and Waltraut Feindt, 1969). Migration is therefore becoming less and less selective. It appears then that many persons move to the city with the expectation of finding long-term employment in the *U-S* sector,<sup>8</sup> and that

---

enterprise in Latin America often set educational requirements (credentials) of some sort for all positions, even though the actual performance of tasks may require little formal education" (1973, p. 17). When writing on the topic of education, Todaro noted that scarce jobs are often allocated on the basis of ever increasing educational "credentials" (1979, pp. 250–51). Malcolm Gillis et al. refer to the process as "educational deepening" (1983, p. 221), and R. M. Sundrum allows that education used as a screening device has a perverse economic impact (1983, p. 89). Whatever the term, it is clear that education prerequisites constitute serious barriers to *U-M* sector employment.

<sup>7</sup>It should be noted that Todaro's work had its empirical base in East Africa, and especially Kenya.

<sup>8</sup>This is not in contradiction of previous studies that found a positive correlation between educational attainment and migration. The greater an individual's educational attainment, the less likely is rural employment that will compensate for the human capital investment. Therefore, the higher the average level of rural education, the greater will be the level of outmigration, *ceteris paribus*. Both data on education and data on migration

their decision is based upon information obtained through a system so thorough and intricate that anthropologists label it a network.<sup>9</sup> The Todaro model, on the other hand, posits that urban emigres are attracted by prospects of employment in the *U-M* sector. It therefore explains the movement of migrants who deem themselves to possess the qualifications necessary for such employment. It does not explain the movement of those intent upon *U-S* sector employment. Indeed, persons migrating in the face of zero probability of employment in the *U-M* sector must be seen as irrational by the Todaro model.

### III

In approaching Todaro's treatment of the *U-S* sector, we begin by investigating his specification of the probability of obtaining *U-M* employment. Specifically, the Todaro formulation for the probability of being selected from the urban "surplus labor" pool during any one time period  $\pi(t)$  is<sup>10,11</sup>

$$\pi(t) = \gamma N_u(t) / (N(t) - N_u(t)),$$

reflect dual phenomena, however. In rural environs, the average level of education grows as does the number of uneducated. Both educated and uneducated join the trek to the cities.

<sup>9</sup>This is described in detail in Lomnitz.

<sup>10</sup>This is parallel to equation (6) in Todaro's seminal work (1969).

<sup>11</sup>The probability term  $\pi$  is closely related to the probability,  $P$ , that is found in fn. 2. In any given time period, the probability of being employed in the *U-M* sector,  $P(t)$ , is related to the probability,  $\pi$ , of having obtained employment in that or any previous time period. This is shown in the following (Todaro, 1979, p. 202):

$$P(x) = \pi(1) + \sum_{t=2}^x \pi(t) \prod_{s=1}^{t-1} [1 - \pi(s)]$$

where  $x$  is the number of time periods and where employment selection is random so that  $\pi(t)$  equals the number of job openings in period  $t$  divided by the number of job aspirants in that period. The probability of obtaining modern sector employment is therefore seen as improving over time.

where  $\gamma$  is the rate of growth of employment in the *U-M* sector,<sup>12</sup>  $N$  represents the total urban labor force, and  $N_u$  is the employed *U-M* labor force.

Although the specification appears straightforward, Todaro displayed indecision in his interpretation of that urban labor component not employed in the modern sector,  $N - N_u$ . At one point, this term is explicitly held to represent "a large pool of unemployed and underemployed who arrived in town earlier and still are waiting for a modern sector job" (1969, p. 142). This labor pool is several times referred to as the "urban traditional sector"; more or less corresponding to what we label as the *U-S* sector. However, the term  $(N - N_u)/N$  is also formally defined as the unemployment rate.<sup>13</sup> With regard to the internal logic of the model, it may not matter which rubric attaches to that part of the urban labor force not employed in the *U-M* sector. In terms of empirical relevancy, however, it makes a world of difference. Rates of open unemployment tend to be relatively low while the *U-S* sector tends to be relatively large and growing. In the Metroplex, for example, open unemployment was around 4 percent at a time when the *U-S* sector accounted for about 34 percent of the urban labor force. At the same time, employment in the *U-M* sector of the Metroplex was growing at an annual rate of 3.6 percent. If the unemployment rate was used to calculate  $\pi$ , the probability of a migrant finding a *U-M* job in the subject year would have been .86. On the other hand, if the *U-S* sector was used as Todaro's  $N - N_u$ ,  $\pi$  would have been .084. In the former case, a migrant's prospects for *U-M* employment would have been quite good; in the latter case, they would have appeared dim.

<sup>12</sup>Where  $\lambda$  is the rate of growth of industrial output and  $\rho$  is the rate of labor productivity growth,  $\gamma = \lambda - \rho$ .

<sup>13</sup>See the discussion pertaining to equation (10) in Todaro (1969). Elsewhere, Todaro makes the straightforward statement that "the probability of obtaining an urban job is inversely related to the urban unemployment rate" (1976, p. 196). A number of empirical tests of the Todaro model have utilized open unemployment (Todaro, 1976, pp. 68 ff.).

TABLE 1—PROBABILITY ( $\pi$ ) OF IMMEDIATELY OBTAINING A *U-M* JOB

$\gamma$	$(N - N_u)/N$					
	.05	.10	.20	.30	.40	.50
.01	.19	.09	.04	.02	.02	.01
.02	.38	.18	.08	.05	.03	.02
.03	.57	.27	.12	.07	.05	.03
.04	.76	.36	.16	.09	.06	.04
.05	.95	.45	.20	.12	.08	.05
.06	1.14	.54	.24	.14	.09	.06
.07	1.33	.63	.28	.16	.11	.07

Note:  $\gamma = \lambda - \rho$ , when  $\lambda$  is the annual rate of growth of industrial output and  $\rho$  is the annual rate of growth of labor productivity in the *U-M* sector.

We will further assess the explanatory range of the Todaro model through exercises that assign a range of plausible values to several of Todaro's variables. In Table 1, several reasonable annual rates of employment creation,  $\gamma$ , are combined with a range of values for the relative size of urban surplus labor pool to produce possible values of  $\pi$ , the probability of obtaining a *U-M* job in the immediate period.

Because development includes growth of labor productivity, widely observed annual growth rates of from 5 to 10 percent for *U-M* sector output likely promote annual employment growth,  $\gamma$ , in the range of 2 to 7 percent. If the surplus labor pool from which *U-M* hiring takes place is defined as open unemployment, then values for  $(N - N_u)/N$  of .05 or .10 would probably be relevant. For those combinations of  $\gamma$  and  $(N - N_u)/N$ , the values for  $\pi$  are relatively high, but because rates of open unemployment are used, the model, in this instance, cannot explain the existence, size, or growth of the *U-S* sector. On the other hand, if the surplus labor pool is held to be the *U-S* sector, then values for  $(N - N_u)/N$  of 30 to 50 percent more likely apply. In those cases the more plausible values for  $\pi$  are observed to be quite low.

It will now be appropriate to relate  $\pi$  to expected income. In Table 2, we combine a range of representative values for  $\pi$  (taken from Table 1) with various possible rates of time-preference discount  $r$ , and determine the number of years that would be required before the present value of expected urban earnings would equal the present value of

TABLE 2—YEARS REQUIRED TO ELIMINATE PRESENT VALUE DIFFERENTIALS

$\pi$	$r$		
	.05	.10	.15
.03	> 50	> 50	> 50
.06	38	> 50	> 50
.09	20	33	> 50
.12	12	16	28
.15	10	11	13
.18	8	8	9

expected rural earnings in a situation where the *U-M* wage rate is twice that of the rural sector.<sup>14</sup> The values chosen for  $\pi$  imply that the *U-S* sector is the pool from which new hires are drawn for the *U-M* sector.<sup>15</sup>

<sup>14</sup>The solutions relate to the values of  $\pi$ , drawn from Table 1 and held constant in each of the time intervals, to selected values of  $r$ , the time-period-preference discount factor, and to a modern wage that is twice the rural wage. Present value calculations are based on the equation for  $V(0)$  found in fn. 2. The probability term  $P(t)$  found in that equation relates to  $\pi$  in the manner specified in fn. 11. As with Todaro, the rural employment probability is considered to be unity. Because the Todaro model calculates incomes in real terms, future earnings are converted to constant currency of the base period. The time-preference rate,  $r$ , used to determine the present values of future income streams should therefore be stated in market values for the base period,  $t(0)$ . If "real pesos" refer to purchasing power in  $t(0)$ , then a real peso earned at some future time might properly be discounted by a real interest rate.

<sup>15</sup>In Todaro's model, new hires are selected at random from the surplus labor pool,  $N - N_u$ . One can conceptualize a more elaborate Todaro model which utilizes various values for  $\pi$  based upon respective stocks of human capital of several groups of potential migrants.

TABLE 3—CHARACTERISTICS OF THE BASIC SECTORS

	Urban Modern	Urban Subsistence	Rural Subsistence
1) Type of employment	Modern nonmenial jobs in manufacturing and modern services	Domestic service, petty trades, handicrafts, repair menial labor services	Operators of very small-scale farms and landless laborers
2) Average productivity and income	High and growing	Low and stagnant	Low and stagnant
3) Barriers to employment	High: largely based on education and cultural background	Few if any	None

It can be seen that the number of years required for equalization of expected urban and expected rural earnings is higher for a given  $r$ , the lower is the value of  $\pi$ . And, for a given  $\pi$ , the higher the value of  $r$ , the further the break-even point moves into the future. It is interesting that the empirical literature spawned by Todaro's work gives little if any attention to the impact of  $r$ . Given the relatively high risks associated with LDC economic activity, the range of  $r = .05$  to  $r = .15$  would appear relevant. It becomes obvious that for many plausible situations, extremely long time horizons must be assumed if the Todaro model is to explain why a potential migrant with little education decides to take his chances in the urban modern labor market. If one must assume very long time horizons, in some cases greater than 50 years, an alternative explanation of migration may be in order.

#### IV

The following analysis is based on recognition that rural-urban migration is a dual phenomenon. Some migrants, those possessed of the requisite human capital, are bound for the  $U-M$  sector. Those who are less well endowed are intent on employment in the  $U-S$  sector. This recognition, in turn, requires some formal description of both the  $U-S$  and  $U-M$  sectors and of the rural sector from which the migrants are drawn. Table 3

presents the important features of the three relevant sectors. One sector of note in most developing countries is not shown in the table. Reference is to a modern rural sector composed of relatively large and relatively mechanized farms. Because the modern farms employ only a small proportion of the labor force and because the wage in that sector tends to be determined in the more populous rural subsistence sector, migration flows that originate or terminate in the modern rural sector have not been considered.<sup>16</sup> Although not formally incorporated into the model, the presence of a modern rural sector will be seen as important for the analysis.<sup>17</sup>

Contrasting with the advanced technology of the emerging  $U-M$  sector are the simple techniques of both subsistence sectors. Because of capital scarcity, the  $U-S$  sector and its rural counterpart feature low levels of productivity and incomes. And, as already discussed, the barriers to employment in the  $U-M$  sector are very high while there are few if any significant barriers to employment in either of the subsistence sectors.<sup>18</sup> This latter

<sup>16</sup>It is worth noting that the Todaro model apparently assumes that all of agricultural labor is found in a traditional or subsistence sector. He argues that institutional factors such as "traditional crop-sharing activities" dominate the rural sector (1969, p. 142, fn. 7).

<sup>17</sup>See fn. 41 below and the discussion to which it pertains.

<sup>18</sup>What is here called the  $U-S$  sector appears in other contexts in the literature and is labeled and defined variously. To some, the sector subsumes all employment not enumerated in official statistics. This often appears as a descriptive characteristic of what is called the informal sector (John Weeks, 1975). For some countries, however, and Mexico is an example, official statistics

It is apparent, however, that those many persons with no human capital would face zero probability of  $U-M$  employment.

fact means that the labor supply in the *U-S* sector is directly affected by conditions in the rural subsistence (*R-S*) sector.

As a basis for developing a formal model, it is necessary to recognize that a portion of *U-S* sector production is exported, so to speak, to other sectors while food and some manufactured goods are imported. For example, about 80 percent of all spending by low-income households in the Metroplex goes for food and clothing (Secretaria de Industria and Comercio, 1962, p. 111). Low-income urban households are not engaged in food production and it has been widely observed that clothing, footwear, and housewares from modern factories have increasingly been replacing the handicraft and artisan items traditionally produced within the *U-S* sector. These modern manufactured goods are imported from the *U-M* sector, and foodstuffs originate in the rural sectors, often passing through *U-M* intermediaries.

A capacity to import implies that the *U-S* sector also produces for export to other sectors. A formal conceptualization of the *U-S* sector must therefore recognize that some of that sector's employment produces goods and services to be consumed by households within the sector while the remainder produces exports for other sectors, largely the *U-M* sector. For the most part, those exports are in the form of menial labor services.<sup>19</sup> Even in

the case of handicrafts, so little capital is involved that value-added by the *U-S* sector is essentially due to the labor input. The *U-S* labor force therefore comprehends all urban persons employed at very low wages, whether found in the petty trades and handicrafts, in domestic service in *U-M* households, or as menials in otherwise modern factories or service establishments. A busboy at the Jockey Club is therefore categorized as a member of the *U-S* sector although his place of employment may appear conspicuously modern.<sup>20</sup> In this manner, the *U-S* labor force is made largely commensurate with urban poverty.<sup>21</sup>

## V

Because rural-urban migration is dual in nature, the migration rate is a composite of

---

*R-S* sector are largely produced in the *U-M* sector. There is, however, some derived demand for *U-S* labor, depending on the extent to which *U-M* firms employ menial labor. The rest of the world may import some of the output of handicraft industries and tourist use of hotel and restaurant facilities effects a derived demand for menial labor services. On the whole, however, the bulk of *U-S* sector exports are destined for the *U-M* sector and are largely in the form of labor services.

<sup>20</sup> For a detailed listing of occupations for Metroplex shanty town dwellers see Lomnitz (pp. 64-65). Some earnings data are illustrative. In the Metroplex, 65 percent of unskilled construction workers earned below the legal minimum wage in 1970, as did more than 90 percent of female service workers (Muñoz et al., p. 84).

<sup>21</sup> When it is recognized that certain employment categories in otherwise modern firms are of menial type, it is no longer reasonable to use the nature of the enterprise as the basis for delineating the modern and subsistence components of the labor force. A maid in a modern household is not considered a part of the modern labor force, nor is the force of grounds keepers at a modern manufacturing plant. The latter, using machetes to trim shrubs and shears to mow lawns, are essentially labor power substitutes for modern equipment just as maids are substitutes for modern appliances. This approach contrasts with convention. According to Sethuraman, "It is the enterprises and not the individuals in the urban economy that are classified into formal and informal sectors" (p. 71). Accordingly, a chambermaid in a modern hotel, earning a subsistence wage and residing in a shanty town, would be classified as a member of the formal or modern sector. Paulo Souza and Victor Tokman (1976, p. 359), however, apparently agree with us to the extent of including domestic servants as part of the informal sector.

---

attempt to enumerate all employment, even that of a marginal nature. For others, small-scale and/or family ownership are important distinguishing characteristics (S. V. Sethuraman, 1976). The informal sector is also taken to include those firms that operate either outside the law or in contravention of the law. This aspect appears in most definitions of the informal sector. Access to foreign exchange and relative labor intensity are also sometimes included in definitions of the sector. Barbara Harriss notes that "Almost all definitions [of the informal sector] contain arbitrary elements, run into tautology and have been found to be operationally controversial" (1978, p. 1077). Characteristics included by one definition are often ignored by others; none is sufficiently comprehensive. Moreover, none of these taxonomic systems provide the basis for a theoretical exploration of intersectoral relationships.

<sup>19</sup> The *R-S* sector is not a significant importer of labor services from the *U-S* sector, nor is the rest of the world. The manufactured goods, clothing, shoes, paper products, plastic wares, and the like, imported by the

migration into the two urban sectors. Thus,

$$(1) \quad (\dot{N}/N)(t) = (\dot{N}_m/N)(t) + (\dot{N}_{us}/N)(t)$$

recalling that  $N$  is the existing size of the urban labor force; and where  $\dot{N}$  represents net rural-urban migration. The subscripts  $m$  and  $us$  represent, respectively, the urban modern ( $U-M$ ) labor force and the urban subsistence ( $U-S$ ) labor force.

As did Todaro, we show migration into the  $U-M$  sector governed by the difference between the discounted streams of expected  $U-M$  and  $R-S$  real incomes, expressed as a percent of the discounted stream of expected rural income. Therefore,

$$(2) \quad (\dot{N}_m/N_m)(t) \\ = F[(V_m(t) - V_{rs}(t))/V_{rs}(t)], \quad F' > 0,$$

where  $V_m(t)$  is the discounted present value of the expected  $U-M$  real income stream over an individual's planning horizon; and  $V_{rs}(t)$  is the discounted present value of the expected real income stream in the  $R-S$  sector over the same planning horizon.

This is essentially the basic Todaro equation, but in the present context, it treats only those migrants bound for the  $U-M$  sector.<sup>22</sup>

For migrants who do not meet the human capital requirements of  $U-M$  work places, migration can be expressed as some function of the earnings differential between  $R-S$  and  $U-S$  sector employment.

$$(3) \quad (\dot{N}_{us}/N_{us})(t) \\ = F[(V_{us}(t) - V_{rs}(t))/V_{rs}(t)], \quad F' > 0,$$

where variables are defined in parallel fashion to those in equation (2). Equation (3) therefore explains the movement of all migrants who are not the subject of equation (2).

<sup>22</sup>This equation is very similar to equation (1) in Todaro's seminal article (1969). As in Todaro, it is assumed that all potential migrants have identical planning horizons; and, utilize constant and identical discount factors.

It will be noted that a common labor supply factor,  $V_{rs}$ , is found in both migration equations. A behavioral equation for that term can be formulated as follows:

$$(4) \quad V_{rs}(0) = \int_{t=0}^n Y_{rs}(t) e^{-rt} dt,$$

where  $Y_{rs}$  represents net income in the  $R-S$  sector (probably institutionally determined) in period  $t$ ,<sup>23</sup> and  $r$  is the appropriate consumption time-preference rate of discount.

By including  $V_{rs}$  as a labor supply factor for both streams of migrants, we are making the realistic assumption that the  $R-S$  wage tends to dominate the rural economy because few rural employment opportunities utilize human capital. We therefore consider that all potential rural emigrants use the  $R-S$  wage as their benchmark.

Focusing now on migrants bound for the  $U-M$  sector, we must consider an employment probability factor and also decide how to treat human capital. Because barriers to  $U-M$  employment are stated in terms of human capital, it is obviously a crucial factor. On the other hand, if the short run is of interest, investment in human capital is a sunk cost and therefore irrelevant to the migration decision. Where human capital would be useful is in explaining changes over time in migration rates. Our interest, however, like that of Todaro, will be the explanation of short-term migration decisions. Defining the short run as a period in which a potential migrant's stock of human capital is fixed and letting  $V_m(0)$  represent the present value of that person's perceived  $U-M$  earnings stream,

$$(5) \quad V_m(0) = \int_{t=0}^n P(t) Y_m(t) e^{-rt} dt - C(0),$$

where  $Y_m(t)$  represents net  $U-M$  real income in period  $t$ ,  $P(t)$  is the probability of having a  $U-M$  job in period  $t$ , and  $C$  is the one-time cost of the migratory move.

<sup>23</sup>See fn. 40 and equation (11) below.

The value  $V_m(0)$  therefore increases with increases in either  $P(t)$  or  $Y_m(t)$ , as in the Todaro case. If interest were in explaining migration over longer periods of time, human capital costs would be added to equation (5).<sup>24</sup>

The inclusion of a probability factor allows that at any point in time there may be an excess of  $U-M$  bound immigrants over  $U-M$  sector employment opportunities. Those educated migrants not initially obtaining  $U-M$  jobs, may either remain temporarily employed or find interim employment in the  $U-S$  sector. Based on considerable evidence it appears likely that many of the highly educated will accept temporary unemployment rather than take menial jobs.<sup>25</sup> To simplify the analysis we will assume that all  $U-M$  bound migrants who fail to find  $U-M$  employment, accept temporary unemployment.<sup>26</sup> Therefore, the probability factor  $P$  in equation (5) varies with the rate of open unemployment in the  $U-M$  sector.<sup>27</sup>

<sup>24</sup>In cases where the  $U-M$  sector is the focal point, the short-term migration decision presupposes a prior decision to invest in human capital. In its turn, that investment decision would have involved comparing expected future gains from migration with the opportunity cost of acquiring the requisite stock of human capital. From this view, the opportunity cost of education would be an important policy variable.

<sup>25</sup>Gunnar Myrdal develops this argument and concludes that "[the educated] are looking for nonmanual work and are not prepared to accept work that 'soils their hands'" (1968, pp. 1124 ff.).

<sup>26</sup>This assumption is necessary if we are to analyze the behavior of those migrants possessed of minimal human capital endowments. It has a strong basis in reality, however, being exemplified by the widespread phenomenon known as the educated unemployed. For those who have acquired relatively advanced schooling, employment in the  $U-S$  sector is considered demeaning. Further, those who could afford the opportunity cost of formal education are more likely to be able to afford temporary unemployment.

<sup>27</sup>Here  $P$  is related to  $\pi$  as shown in fn. 11, but, in this case,

$$\pi(t) = \gamma N_u(t) / (M(t) - N_u(t)),$$

where  $M$  is the total  $U-M$  labor force,  $N_u$  the employed  $U-M$  labor force, and  $\gamma$ , the rate of employment creation in the  $U-M$  sector (see Section III).

Because no human capital is required for employment in the  $U-S$  sector, the probability of employment at the existing  $U-S$  wage is unity for any given individual so that the present value of expected  $U-S$  sector earnings,  $V_{us}(0)$ , may be represented by

$$(6) \quad V_{us}(0) = \int_{t=0}^n Y_{us}(t) e^{-rt} dt - C(0),$$

where  $Y_{us}(t)$  represents net  $U-S$  real income in period  $(t)$ .

As in the Todaro case,  $U-M$  earnings,  $Y_m(t)$ , are determined by institutional factors.<sup>28</sup> However, because of the ease of entry, the  $U-S$  earnings,  $Y_{us}(t)$ , will tend to vary with the determinants of labor supply and labor demand. If we are to gain further understanding of the subsistence component of rural urban migration, we must pursue those determinants.

## VI

We follow Todaro's lead and consider labor supply to be exogenous.<sup>29</sup> Because of freedom of entry into the  $U-S$  sector and population pressure on rural land, labor supply for the  $U-S$  sector is considered to be perfectly elastic.<sup>30</sup> Analysis of labor demand requires specification of the determinants of output in the respective subsistence sectors. For the  $U-S$  sector, the production function is simple:

$$(7) \quad Q_{us} = F(N_{us}),$$

where  $Q_{us}$  and  $N_{us}$  denote output volume and size of the  $U-S$  labor force, respectively. Output is in the form of labor services and capital is assumed to be of scarcely any importance.

<sup>28</sup>Reference is usually to administered wages which are held to be significantly above the social opportunity cost of new hires.

<sup>29</sup>Population growth is a principle supply factor along with the labor force participation rate and the age structure of population. It would serve no useful purpose to include these in the model.

<sup>30</sup>For a discussion of the rural labor condition, see fn. 36 and the text to which it pertains.

In converting *U-S* sector output to income, two important identities emerge:

$$(8) \quad Y_{us} = P_{us}Q_{us} = \hat{W}_{us}N_{us}$$

$$(9) \quad Y_{us} = P_{us}(X + G),$$

where  $Y_{us}$ ,  $\hat{W}_{us}$ , and  $P_{us}$  are, respectively, total income, money wage, and price of labor services; and  $X$  and  $G$ , respectively, represent the volume of labor services sold as exports to the *U-M* sector and the volume of *U-S* output consumed within the *U-S* sector.<sup>31</sup>

The identity in equation (8) simply recognizes that because the output of the *U-S* sector is in the form of labor services, price and wage are different sides of the same coin. Equation (9) stipulates that a portion of the output of the *U-S* sector is exported, with the remainder consumed within the sector. This presents us with a useful perspective on *U-S* sector income. Indeed, if we assume that barter is inconsequential in the urban setting and that exports are the source of the circulating money supply in the *U-S* sector, the money value of exports largely determines the level of *U-S* sector income.<sup>32</sup> Whereas exports increase the income stream, imports of food and manufactured goods constitute leakages. Because there is little if any capital stock, we may assume there is no saving. The open economy multiplier for the *U-S* sector therefore depends solely upon the propensity to import. It then follows that the level of *U-S* sector income is based upon the money value of exports and the average propensity to import.<sup>33</sup> That income stream derived from

exports and expanded by a multiplier effect also finances consumption of some *U-S* sector value-added by *U-S* sector households.<sup>34</sup>

The most important determinants of demand for *U-S* exports are population and per capita income in the *U-M* sector, and the prices of capital goods that substitute for *U-S* labor. Where  $X$  represents the quantity of *U-S* exports demanded by the *U-M* sector, then

$$X = f(P_{us}, P_F, Y_m, Pop),$$

where  $P_{us}$  is the price of *U-S* labor service exports (*U-S* wage), and  $P_F$  represents the price of manufactured substitutes for *U-S* labor. Also,  $Y_m$  represents income per capita in the *U-M* sector and  $Pop$  stand for *U-M* population. If one were to understand the long-run impact of the *U-M* sector on *U-S* sector employment and rural-urban migration, the focus should be upon the nonprice variables.<sup>35</sup> At any point in time, however, the quantity demanded is a function of  $P_{us}$ , which, as we have seen, is the same as  $\hat{W}_{us}$ .

Given a demand schedule, any change in the *U-S* wage will affect the quantity of *U-S* exports and, depending on price elasticity, the total value of exports. This impact of price elasticity on the total value of exports, in turn, has implications for wage and employment. Indeed, *U-S* exports, *U-S* wage, and *U-S* employment are simultaneously determined. To establish this point it is necessary to include the *R-S* sector in the analysis

<sup>31</sup>A discussion of the export of labor services from the *U-S* sector was presented in Section IV.

<sup>32</sup>If we make the largely realistic assumption that the *U-S* sector is not privy to credit emanating from a fractional reserve system, then  $Y_{us} = \hat{X}V$ , where  $\hat{X}$  is the money value of exports, and  $V$ , the velocity of circulation.

<sup>33</sup>Indeed, if we assume balanced trade between the *U-S* sector and other sectors,  $Y_{us} = \hat{X}/APM$ , where  $\hat{X}$  is the money value of exports and  $APM$  represents the average propensity to import. (For changes in  $Y_{us}$ , the marginal propensity to import would be appropriate.)

Also note that  $\hat{X}V = Y_{us} = \hat{X}/APM$  (see fn. 32). It was noted earlier that 80 percent of expenditures by *U-S* households in the Metroplex went for imports. In that case, the export multiplier would be 1.25 and  $\hat{G}$  would be equal to .25 $\hat{X}$ . Other works have made reference to an export multiplier in a similar *LDC* context (Keith Hart, 1983), but the argument has not been rigorously developed.

<sup>34</sup>Because very little capital is involved, even that *U-S* sector value-added consumed by *U-S* sector households can be fairly said to consist very largely of labor input.

<sup>35</sup>An area of untapped research potential is the relationship of demand for labor services to the price of manufactured substitutes for those services.

because the absence of barriers to entry permits labor to move more or less freely between it and the *U-S* sector.

The output equation for the *R-S* sector can be represented as

$$(10) \quad Q_{rs} = f(N_{rs}, L_{rs}, K_{rs}),$$

where  $Q_{rs}$ ,  $N_{rs}$ ,  $L_{rs}$ , and  $K_{rs}$  denote, respectively, output volume, labor, land and capital. In the *R-S* sector, the stock of capital is minimal and possibilities for its expansion are severely circumscribed. Land is essentially fixed and, assuming that labor has a marginal product of zero over a wide range,<sup>36,37</sup>  $Q_{rs}$  would be at a maximum and remain so until land and/or capital bottlenecks were broken.<sup>38</sup>

We follow the standard practice of the literature on economic dualism and assume that the *R-S* real wage,  $W_{rs}$ , is institutionally determined, and is<sup>39,40</sup>

$$(11) \quad W_{rs} = Q_{rs}/N_{rs}.$$

<sup>36</sup>The often-used assumption of zero marginal product is usually based on the existence of a considerable pressure of population on the relevant land and an institutional arrangement that promotes application of family labor so long as returns are nonnegative. Severe population pressure exists in those regions of Mexico furnishing the bulk of rural to urban migrants, and in many other countries as well.

<sup>37</sup>Extreme assumptions such as zero marginal product are sometimes vital to the discovery of fundamental tendencies. Such discoveries, in turn, help to throw light on situations that do not necessarily conform to the extreme assumptions. For example, an empirical model based on the present theory could serve in situations where the marginal product of *R-S* labor is positive, albeit small relative to that of the *U-M* sector.

<sup>38</sup>This maximum is in reality a constraint. There could be shortfalls, of course, caused by natural phenomena. In that case the rural wage would fall, sparking additional rural-urban migration.

<sup>39</sup>This a, a real wage in the sense that it measures physical output and not in the sense that it measures constant purchasing power.

<sup>40</sup>The assumption that wage is equal to average product is reasonable for the collectives and small-scale private farms in Mexico where most labor comes from family members. The assumption can also apply to other Latin American or Asian countries with sharecropping systems by assuming that the return to land ownership is a fixed rent, with the remainder divided among members of the *R-S* labor force.

The money wage, which is used hereafter, is therefore

$$(12) \quad \hat{W}_{rs} = P_r(Q_{rs}/N_{rs}),$$

where  $P_r$  is the exogenously determined price of agricultural output which is assumed constant in the subsequent analysis,<sup>41</sup> and where labor supply is, in effect, perfectly inelastic.<sup>42</sup> With land a fixed input and the marginal product of labor equal to zero over a wide range,  $\hat{W}_{rs}$  will vary inversely with changes in  $N_{rs}$ . In this stylized situation, population growth places downward pressure on  $\hat{W}_{rs}$ . In the classical or Malthusian setting, a downward slide of the wage would ultimately act as a population check. However, in a dualistic setting such as that found in Mexico, there is a potential safety valve in the form of the *U-S* sector.<sup>43</sup>

With *U-S* labor and *R-S* labor considered substitutes, at least across a wide range, it follows that so long as the marginal product of labor in the *R-S* sector is at or near zero, the labor supply in the *U-S* sector will be perfectly elastic at a wage equal to that in the *R-S* sector. We may therefore combine equations (8) and (12) to arrive at the basic

<sup>41</sup>In Mexico, as in many other countries, there is a sizable modern rural sector. Agricultural prices, therefore, are not directly tied to particular changes in subsistence sector variables. It is therefore not desirable to include the intersectoral terms of trade as a variable in the model. A modern rural sector has appeared in previous dualism models (Keith Griffin, 1976).

<sup>42</sup>Population growth is the major supply factor and is taken to be exogenous. So long as institutional factors lead to employment of rural labor force members, the *R-S* labor supply for practical purposes will approach perfect inelasticity, while demand will feature unit elasticity in the relevant range. If, as assumed,  $Q_{rs}$  is at a maximum and  $P_r$  is exogenously determined, the value of *R-S* output is given at  $P_r Q_{rs}$ . In the assumed institutional setting this is also the fixed wage bill (from equation (2), we have  $P_r Q_{rs} = \hat{W}_{rs} N_{rs}$ ). Changes in  $N_{rs}$  are therefore precisely countered as  $\hat{W}_{rs}$  moves in the opposite direction.

<sup>43</sup>Illegal migration to the United States is also a safety valve for the Mexican population. However, a large proportion of the illegal migrants have significant stocks of human capital. For the relatively uneducated and the illiterate, the more likely safety valve is found in urban Mexico.

equilibrium condition shown in<sup>44</sup>

$$(13) \quad \hat{W}_{us} = Y_{us}/N_{us} = P_r(Q_{rs}/N_{rs}) = \hat{W}_{rs}.$$

By making certain assumptions about the costs of migration and discount rates, this equilibrium condition can be stated in terms of present value of expected earnings:  $V_{us} = V_{rs}$ .<sup>45</sup> Any reduction in  $\hat{W}_{rs}$  or increase in  $\hat{W}_{us}$  would therefore affect present value calculations (equation (3)) so as to increase the migratory flow.

Under the stipulated conditions, population pressure leading to labor force growth in either of the subsistence sectors will tend to reduce both the *R-S* and the *U-S* wage. There will be countervailing tendencies, however, the impact of which all depend on the relevant price elasticity of *U-S* exports.<sup>46</sup> To explore the importance of price elasticity, assume that the non-price-demand determinants for *U-S* exports are constant, and recall that  $P_{us}$  is also  $\hat{W}_{us}$ . As population pressure in the subsistence sectors pushes down the *U-S* wage, the quantity of exports demanded will increase, but, depending on the size of the elasticity coefficient, the income stream flowing into the *U-S* sector might swell or shrink. If *U-S* exports are price elastic, for example, the total value of labor services exported would increase as  $P_{us}$  falls, even if population and income in the *U-M*

sector did not grow.<sup>47</sup> In other words, the more price elastic the demand for *U-S* exports, the less will be the downward pressure on  $\hat{W}_{us}$  and the greater will be the expansionary influence on employment of a given labor supply pressure. The expansion of employment in the *U-S* sector is based partly upon the natural rate of population increase and partly upon rural-urban migration. On the other hand, if demand were inelastic, a falling *U-S* wage would reduce the total value of *U-S* labor service exports. In that case, supply pressure would cause a relatively large decrease in  $\hat{W}_{us} = \hat{W}_{rs}$ , and a relatively small increase in *U-S* sector employment.<sup>48</sup>

## VII

We have seen that wage and employment in the *U-S* sector are intimately tied to developments in other sectors. The *U-S* labor supply is greatly affected by conditions in the *R-S* sector and the demand for *U-S* labor largely emanates from the *U-M* sector. The exports associated with the demand for labor services result in a flow of payments into the *U-S* sector, the size of which is affected by the price elasticity of the labor exports.<sup>49</sup> The value of that flow, in turn, is

<sup>44</sup>Recall that  $Q_{rs}$  is at a maximum and that  $P_r$  is exogenously determined and assumed constant for the analysis. In reality the equilibrium might be achieved without equating money wages. We recognize that psychic return and/or cost of living might vary across sectors, but prefer to keep the analysis clear-cut by abstracting from such considerations.

<sup>45</sup>See equations (3), (4), and (6). The equilibrium  $\hat{W}_{us} = \hat{W}_{rs}$  would yield an equilibrium  $V_{us} = V_{rs}$  if the cost of migration were zero and time-preference discount rates were the same for rural and urban earnings. Given some cost of migration, when  $V_{us} = V_{rs}$ , then  $\hat{W}_{us} > \hat{W}_{rs}$ . Although it would complicate the exposition, the cost factor could be added to the analysis.

<sup>46</sup>In the classical surplus labor models, the rural subsistence wage determines the urban wage (W. Arthur Lewis, 1954). In the present model a common subsistence wage is determined by simultaneous changes in the *U-S* and *R-S* sectors.

<sup>47</sup>Having assumed *U-M* employment and income constant, the increased value of *U-S* exports would mean that *U-S* labor services have been substituted by the *U-M* sector for other goods and services. The *U-M* sector could increase its imports within the constraint of a constant level of income ( $Y_m = P_m Q_m$ ) so long as there were no savings in the *U-S* sector (the assumed condition). The *U-S* sector would therefore increase its imports of *U-M* sector products sufficiently to maintain balanced intersectoral trade, however, at a higher level.

<sup>48</sup>There have been virtually no attempts to estimate the price elasticity of the labor services of the type exported by the *U-S* sector. To the extent that the present analysis is useful, this topic should be added to the research agenda. In the absence of data, one is tempted to speculate that domestic service, for example, is price elastic, being in the nature of luxury.

<sup>49</sup>The extent to which growth in the *U-M* sector leads to *U-S* employment opportunities also depends on the income elasticity of *U-M* sector demand for *U-S* exports. There is a paucity of data on that subject. Dealing with combined demand of all urban sectors, one study suggests that the income elasticity coefficient varies from a low of less than 0.5 to well over 1.0 (Paul Mosley, 1978, p. 7). The data, however, did not treat

enhanced by a multiplier effect to create additional employment within the *U-S* sector.

Here then are the keys to understanding that portion of rural to urban migration that has resulted in burgeoning growth of urban subsistence sectors: 1) the growth of the subsistence population, which keeps downward pressure on the subsistence wage, and 2) the rapid growth of the *U-M* sector which has translated into the growth of demand for exports from the *U-S* sector. Where the Todaro model explains why those who possess human capital migrate, our model explains why masses of unschooled and relatively unskilled persons also join the trek to the city. They move when population pressure on fixed agricultural land reduces the rural subsistence wage significantly below that of the *U-S* sector, or when growth of demand for *U-S* exports pushes the wage in that sector significantly above that of the rural subsistence sector.<sup>50</sup> For many of those caught up in the urban trek, the focus is not on the modern sector with its relatively high wages, but rather on the subsistence sector with its relative ease of entry. The present analysis is therefore a useful complement to the Todaro theory of migration.

### VIII

Although the Todaro model is unidimensional while migration is a dual phenomenon, that model generally has been found consistent with the data. Consistency with the data, however, is not sufficient if the theory is inappropriate. It is the theory that informs policy. If the focus is growth of the *U-S* sector labor force, the Todaro model has yielded the correct prediction, but has failed to provide a satisfactory explanation.

---

domestic service or menial labor, categories crucial to this study.

<sup>50</sup>In reality, forces other than population also affect the rural wage. Various market and institutional forces may cause changes in prices for rural output. Recall, however, that we chose to hold rural prices constant in order to establish the basic relationships between the *R-S* and *U-S* sectors.

That theory, in turn, has lead analysts to the seemingly fatalistic view that attempts to solve the urban employment problem are likely to make the situation worse. This unintentional result is said to occur because the creation of new workplaces in the *U-M* sector enhances the probability of *U-M* employment, thereby promoting increased migration. Given the relatively large size of the rural labor force, the number of rural to urban migrants is likely to exceed the number of new modern sector workplaces. In that fashion, policies to promote urban economic modernization are said to lead to increased urban unemployment and underemployment (Todaro, 1979, p. 197). From that viewpoint, the market appears perverse. Decisions that are rational from the point of view of individuals appear disastrous for society. Those analysts are then forced to the conclusion that the solution to the urban employment problem must be sought in the rural areas. For example, it has been argued that "The present unnecessary economic incentives for rural-urban migration need to be minimized through creative and well-designed programs of integrated rural development" (Todaro, 1979, p. 198).<sup>51</sup> The perversion of the market is taken to be so extreme that some have been pushed to consider direct restrictions on migration such as those found in Tanzania and South Africa.<sup>52</sup>

<sup>51</sup>On the basis of the present analysis, it is appropriate to question whether investment directly in the rural sector would create ancillary employment of the nature and magnitude of that related to investment in the *U-M* sector. One is likely to find little demand for servants, plumbers, appliance repair shops, street vendors, news hawkers, boot blacks, or even small restaurants in agricultural villages. Finally, it is likely that the urban setting provides economies of scale in the delivery of education, health care, and family planning. There is the opportunity, therefore, for policymakers to take advantage of the rural to urban migration to reduce the population growth rate, on the one hand, and to improve the quality of the labor force, on the other. Rather than trying to stand against the tide, a reasonable policy emphasis might otherwise take advantage of the massive movement of humanity.

<sup>52</sup>While maintaining "grave reservations about the ethical issues involved," John Harris and Todaro (1970, p. 135) investigate the economic implications of direct restrictions on migration.

If one's viewpoint, however, includes the revised paradigm presented here, much of the recent rural-urban migration appears desirable from society's perspective as well as from that of individual migrants. The migration would be seen as socially undesirable only if one could show that a significant fraction of migrants produced in the urban setting less than would have been the case had they remained in rural environs. The facts appear to be otherwise, however. Because urban modern employment is likely for educated migrants, their movement contributes directly to economic growth.<sup>53</sup> In turn, the growth of the *U-M* sector fuels demand for *U-S* sector exports. The growth of the demand imparts a tendency for wage to increase in the *U-S* sector which, *pari passu*, sparks urban-bound migration into that sector. That migration itself improves the overall productivity of the economy and enhances the welfare of both those who migrate to the urban subsistence sector and those who remain in the rural subsistence sector.

<sup>53</sup>It can also be argued that those of the educated migrants who initially fail to find urban employment would not have been willing to work in the rural setting (see fn. 25). This might lead one to question the efficacy of having educated them, but that is another matter.

# Accounting Rates of Return

By GERALD L. SALAMON\*

Many economic studies provide empirical evidence regarding cross-sectional differences in firm profitability. In most of these studies, firm profitability is measured by an accounting rate of return (net income dividend by the book value of assets, hereafter, *ARR*) rather than an economic rate of profit.<sup>1</sup> Franklin Fisher and John McGowan define the firm's economic rate of profit (*IRR*) as that interest rate which "equates the present value of its net revenue stream to its initial outlay" (1983, p. 82). Fisher and McGowan examine the analytic relation between a firm's *ARR* and its *IRR* in a series of examples and conclude that the *ARR* is such a bad surrogate for the *IRR* that the results of *ARR*-based empirical studies are likely to be "totally misleading" (p. 91).

William Long and David Ravenscraft (1984) have criticized the theoretical work of Fisher and McGowan because the nature of the analytic relationship between the *ARR* and the *IRR* in the context of highly simplified hypothetical "examples" may not be indicative of the nature of the relationship in empirical settings. Their criticism adopts the utilitarian view that the *ARR* has to be treated as a suitable surrogate for the *IRR* as long as no preferable alternative measure of profitability is available for empirical work.

This view has merit as long as the measurement error which is contained in the *ARR* is random rather than systematic. Unfortunately, the nature and extent of the measurement error which is contained in the *ARR* in a particular empirical setting can only be determined unequivocally if the *IRR* is unequivocally known. In such a case, of course, there would be no need to rely on the *ARR* at all. Due to this unhappy circle, empirical research on firm profitability has continued to rely on the *ARR* despite the fact that many persons reasonably believe that the results of such research may be totally misleading (Fisher and McGowan; G. C. Harcourt, 1965), while others reasonably believe that the results are reliable enough to form a basis for policy decisions (Long and Ravenscraft).

Recent work by Y. Ijiri (1978; 1979; 1980) and by myself (1982) has shown that conditional *IRR* estimates can be obtained from data in firms' financial statements. While these *IRR* estimates are conditional, they do abstract from certain extraneous factors that influence *ARR*s and that differ across firms. Consequently the conditional *IRR* estimates are free from *some* of the sources of measurement error which are known to contaminate the *ARR*. Thus, the conditional *IRR* estimates can be used to provide evidence on whether these sources of measurement error have or have not affected the outcome of prior studies in which profitability was measured by the *ARR*. Such evidence can help to *objectively* resolve the conflict between the opposing views on the reliability of *ARR*-based profitability research.

This paper uses conditional *IRR* estimates to examine the properties of the measurement error in the *ARR* in a study of the relationship between firm profitability and firm size. The remainder of the paper is organized as follows. In Section I, the theoretical work of Fisher and McGowan is used

\*Professor of Accounting, University of Iowa, Iowa City, IA 52242. I gratefully acknowledge the comments of William Albrecht, Dan Dhaliwal, Gary Fethke, Franklin Fisher, Scott Linn, William R. Kinney, Jr., and the participants of a workshop at the University of Florida on earlier versions of this paper.

<sup>1</sup>Some authors (for example, William Long and David Ravenscraft, 1984) have used the sales margin ratio (earnings/sales) as a measure of profitability. However, if one views profitability as return per unit of sacrifice, the sales margin ratio is not a profitability measure since it ignores the sacrifice (or investment) required to generate a dollar of sales. Consequently, this paper does not attempt to shed any insight into prior studies that have relied on the sales margin ratio as a measure of profitability.

as the basis for analyzing the nature of the measurement error in the *ARR* in general and in the context of studies of the relationship between firm profitability and firm size. An outline and an analysis of the procedures for estimating conditional *IRRs* is presented in Section II. In Section III, empirical evidence is presented that documents that the *ARR* contains systematic rather than random measurement error in firm size studies. Finally, in Section IV, a brief summary of the paper is provided and some specific suggestions for future research are made.

### I. Measurement Error and Firm Size

G. Whittington (1979, p. 204) has argued that the *ARR* would be a suitable surrogate for the *IRR* in empirical research if the *ARR* is correlated with the *IRR*, and if the variance of the *ARR* that is unexplained by the *IRR* is uncorrelated with the explanatory variable used in the analysis. If such were the case, then the use of the *ARR* in empirical research would lead to weak but unbiased tests of economic hypotheses. Research that has relied on conditional *IRR* estimates suggests that the *ARR* and the *IRR* are positively associated in most empirical settings (for example, my 1982 article; myself and M. Moriarty, 1984; my 1984 paper with S. C. Linn and W. P. Albrecht). Consequently, the first of Whittington's criteria for satisfactory surrogation appears to be generally met. Unfortunately, it is still unclear whether the second of his conditions is or is not met in general. The essence of the controversy between Fisher and McGowan and their critics (for example, Long and Ravenscraft) appears to center on this single issue. Fisher and McGowan appear to hold the position (based upon their theoretical analysis) that the error in the *ARR* is likely to be systematic in enough settings that the use of the *ARR*, in general, produces results that cannot be relied upon. Long and Ravenscraft, on the other hand, seem to believe that the measurement error in the *ARR* is likely to be random in most settings so that tests of economic hypotheses which rely on the *ARR* are unbiased and thus reliable. At this stage of our knowledge, it is difficult to evaluate the merits of these opposing positions be-

cause of the lack of direct evidence. Furthermore, neither of these two extreme positions is likely to hold in general. In particular, it is likely that the measurement error in the *ARR* will be random in some settings and systematic in other settings. If this is the case, then it would be quite useful to establish guidelines that would allow a preliminary classification of past *ARR*-based research into one set in which the major concern would be the power of the statistical tests and into another set in which the major concern would be the bias of the statistical tests. This paper represents an initial effort to base such guidelines on the outcome of empirical tests of the theory developed by Fisher and McGowan.

Fisher and McGowan demonstrate that the level of a firm's *ARR* is systematically affected by its choice of a depreciation method. Thus, their theory suggests that the nature of the measurement error in the *ARR* in a particular sample of firms will depend upon the distribution of accounting methods across the firms in that sample. In particular, the measurement error in the *ARR* is likely to be systematically related to a potential explanatory variable whenever the choice of accounting methods is systematically related to that variable.

This paper examines the nature of the measurement error in the *ARR* in the context of studies of the relationship between firm profitability and firm size. This area was chosen for examination for two primary reasons. First, the relationship between firm size and firm profitability is a time-honored topic on which well-known scholars have differing opinions. Marshall Hall and Leonard Weiss (1967, p. 329) suggest that William Baumol (1959) believed in the existence of a positive association between firm size and firm profitability while George Stigler (1950) and Joe Bain (1956) expressed either skepticism or uncertainty about such a positive association. Hall and Weiss present empirical results that are consistent with a positive association between firm size and profitability, but profitability in their study was measured by the *ARR*.

The second, and perhaps more important, reason for examining the nature of the *ARR*-based measurement error in the context

of a firm-size study is that prior research has found that there are systematic differences in the accounting methods adopted by firms of different size. For example, R. Watts and G. Zimmerman (1978), D. Dhaliwal, myself, and E. D. Smith (1982), and R. Hagerman and M. Zmijewski (1979) all found that large firms tended to adopt accounting methods that resulted in smaller earnings levels than the earnings levels produced by the accounting methods adopted by small firms.<sup>2</sup> This means, for example, that large firms tend to elect accelerated methods of depreciation more frequently than small firms. The nature of these differences in the depreciation methods of large and small firms is important given Fisher and McGowan's demonstration of how a firm's *ARR* is affected by its choice of a depreciation method. In particular, Fisher and McGowan (Table 2, p. 86) demonstrated that, if the growth rate in investment is less than the *IRR* of firm projects, then the steady-state *ARR* of the firm is higher if it uses an accelerated depreciation method than if it uses the straight-line depreciation method.<sup>3</sup> Thus, the nature of the systematic differences in the depreciation methods adopted by large and small firms is hypothesized to induce systematic rather than random measurement error in the *ARR* in the context of studies of the relationship between firm profitability and firm size.

It is important to notice that the direction of this effect is such that the positive association between firm size and firm profitability that was observed by Hall and Weiss may have been induced by the systematic error contained in their measure of profitability the *ARR*. Consequently, an examination of the properties of the measurement error in

the *ARR* in size-profitability studies has the potential to provide evidence that directly addresses the controversy between Fisher-McGowan and their critics (as represented by Long-Ravenscraft). Clearly, the theory developed by Fisher and McGowan along with the findings of systematic differences in the accounting methods adopted by large and small firms predicts that the *ARR* will contain systematic measurement error in studies of the relationship between firm profitability and firm size. If such systematic error is not documented in this setting then it would appear that the *ARR* is a reasonable general surrogate for the *IRR* in empirical research as was suggested by Long-Ravenscraft. On the other hand, if the *ARR* is found to possess measurement error properties consistent with the predictions of the theory developed by Fisher-McGowan, then their theory cannot be legitimately criticized because of the simplicity of its underlying assumptions. Furthermore, if systematic measurement error is found to be present in the *ARR* in this setting, then the results of *ARR*-based research should be viewed with skepticism whenever there is an association between the explanatory variable of concern and the accounting methods used by the firm.

## II. Conditional Estimates of Firm *IRR*

Ijiri (1978; 1980) has advocated the preparation of financial reports on the cash basis rather than on the accrual basis. Ijiri's emphasis on cash-basis reports has stimulated interest in a variable called the cash recovery rate (*CRR*). The *CRR* is the ratio of the firm's cash recoveries in a period to the gross historical cost of investments outstanding during the period. Under the condition of constant investment growth, my article (1982) has shown that a firm's *CRR* converges to the constant given in equation (1) when the cash flow profile of the firm's projects can be represented by a single parameter.<sup>4</sup>

<sup>2</sup>The studies of accounting method choice and firm size often report significance levels between 5 and 10 percent. See R. Holthausen and R. Leftwich (1983) for a thorough review of the accounting method choice literature.

<sup>3</sup>The case of *IRR* being less than the rate of investment growth is the most common case in practice for the large mature firms which are examined in this paper. See my 1973 article for a demonstration that shareholders are continually increasing their investment in the firm (i.e., they never receive a dividend) whenever the growth rate exceeds the *IRR*.

<sup>4</sup>This equation is similar to equation (4) of my article (1982). Equation (1) above, however, emphasizes the nominal *IRR* rather than the real *IRR*.

$$(1) \quad CRR = g / [(1 + g)^n - 1] \\ \cdot \left[ \frac{(1 + g)^n - b^n}{(1 + g - b)} \right] \cdot \left[ \frac{(1 + r)^n (1 + r - b)}{(1 + r)^n - b^n} \right],$$

where  $g$  = constant growth rate in gross investment,  $n$  = useful life of firm's "representative" composite project,  $r$  = internal rate of return of firm's representative project, and  $b$  = project cash flow pattern parameter. If  $Y_0, Y_1, \dots, Y_n$  are the after-tax cash flows of the firm's representative projects with  $Y_0 < 0$  and  $Y_1, \dots, Y_n > 0$ , then  $b$  is such that  $Y_i = b^{i-1} Y_1$  for  $i = 1, \dots, n$ . Note that if  $b < 1$  ( $>$ ) project cash flows decay (grow) exponentially.

Certain assumptions about the firm and its environment underlie the derivation of equation (1). In particular, each firm is assumed to be a collection of projects that have the same useful life, cash flow profile, and *IRR*. The collection of projects is assembled via a gross investment function that grows at a constant rate per period. It is true, of course, that contrary to these assumptions, firms do not have a constant rate of investment growth and they do invest in a variety of projects with different lives, cash flow profiles, and *IRRs*. However, there are arguments and evidence that suggest that the assumptions made in order to derive equation (1) are not so unrealistic as to prevent it from being used to obtain meaningful empirical *IRR* estimates. For example, Ijiri (1979, p. 261) has observed that a firm can be thought of as a composite project with a given life and cash flow profile as long as the underlying mix of its individual projects is reasonably stable over time. The stable project mix assumption would seem to be a reasonable one for large mature firms since for such firms the impact of new ventures would seem to be relatively small. Additionally, Ijiri (1979) has provided indirect evidence on the issue of cyclical vs. constant rates of investment growth in mature firms. Significant cyclical patterns in investment growth would lead to cyclical patterns in *CRRs*.<sup>5</sup> Ijiri (1978, Table

2, p. 341, and fn. 12, p. 342) presents evidence that the *CRRs* for a sample of mature firms are reasonably time stable. Thus, it appears that the assumptions which underlie equation (1) are not systematically and importantly violated if its use is restricted to samples of mature firms.

Equation (1) allows the empirical estimation of the *IRR* of an on-going firm given estimates of *CRR*,  $g$ ,  $n$ , and  $b$ . The *CRR*,  $g$ , and  $n$  can be reasonably estimated from data in the firm's external financial reports. The cash flow pattern parameter,  $b$ , poses a more difficult problem. In principle, this parameter could be estimated from a regression of cash recoveries on a distributed lag of past investment (Fisher-McGowan, p. 91, fn. 21). However, very little empirical work has been conducted on the cash flow profiles of firm projects because of econometric difficulties associated with distributed lag regressions and because the empirical research on how *IRR* estimates are affected by cash flow profiles is at such an early state of development.

Prior work has sidestepped the problem of estimating cash flow profiles by assuming that all firms have projects with the same cash flow pattern parameter which is assigned a numerical value (see my 1982 article). The fact that the cash flow pattern parameter is assigned a value (and is not estimated) means that the estimates of *IRR* that result from solving equation (1) for  $r$  have to be viewed as conditional rather than as unconditional estimates. While the decision to assign a value to the cash flow pattern parameter does avoid the estimation problem, it does raise questions about how to choose the value which is assigned to the parameter. In a preliminary examination of this issue (1982), I found that the rankings of firms by their conditional *IRRs* was relatively insensitive to the value assigned to the cash flow profile parameter in equation (1). It is not clear, however, whether the insensitivity of *IRR* rankings to different levels of the cash flow pattern parameter will mean that the reported measurement error properties of the *ARR* in a particular setting will also be insensitive to whether the firms' *IRRs* are estimated with different values of the cash flow pattern parameter. Consequently,

<sup>5</sup> See J. L. Livingstone and myself (1970) for a model which leads to cyclical yet convergent *ARRs*.

in this paper, four different conditional *IRRs* were calculated for each firm—each different *IRR* was based upon a different value of the cash flow pattern parameter. The values assigned to the cash flow parameter (*b*) were .8, 1.0, 1.1, and a random assignment from a uniform distribution which was defined on the interval (.8, 1.1). This practice allows this paper to present some preliminary evidence on whether the reported measurement error properties of the *ARR* are sensitive to the cash flow profiles which are assumed when equation (1) is used to convert firms' *CRRs* into estimates of their *IRRs*.<sup>6</sup>

I argued (1982, p. 301) that typical after-tax cash flow patterns would be declining because of the widespread use of accelerated depreciation methods for tax purposes and because of the use of the payback period as a criterion for choosing projects. Consequently, one conditional estimate of the *IRR* of each firm was based on the assumption that project cash flows were declining. For this case, the parameter *b* was assigned the value of .8. A value of *b* less than .8 was not examined because of the fact that most of the firms in the sample had reasonably long project lives. Extremely declining cash flow patterns and long project lives are inconsistent with the choice of an optimal depreciable life for tax purposes. Assigning *b* a value of 1 corresponds to level cash flows over the projects' lives and also results in equation (1) being considerably simplified. In particular, if *b* is equal to 1 then the firm's *CRR* converges to the constant given in

$$(2) \quad CRR = r / [1 - (1 + r)^{-n}].$$

Ijiri (1978; 1980) and myself and Moriarty relied on equation (2) to obtain conditional *IRR* estimates for samples of mature firms. It is noted in this case of level cash flows that the growth rate in the firm's gross investment has no influence on the level of the firm's *CRR*. The cash flow pattern parameter was also assigned the value 1.1 in order to allow

for the case of an increasing cash flow pattern over the life of the projects. So far the assignment of values to the cash flow pattern parameter was done under the assumption that all firms had projects which had the same cash flow pattern. Consequently, while this procedure allowed an examination of how sensitive the results were to different common cash flow patterns, it did not allow a determination of whether the results would be affected if different firms had different cash flow patterns. In order to examine this latter issue, a value was assigned to the cash flow pattern parameter of each firm by taking a random drawing from a uniform probability distribution which had end points of .8 and 1.1. Thus, in this paper four different conditional *IRRs* were estimated for each firm in the sample with each estimate corresponding to a different assumption about the cash flow pattern of the firms' projects. The results of this paper were quite similar for all four conditional *IRR* estimates and consequently only the results based upon the conditional *IRR* estimates which assumed common and level cash flows (labeled *IRR*(1)) and which made a random assignment to the value of the cash flow pattern parameter (labeled *IRR*(ran)) are presented.

In closing this section, it is noted that the *ARR* contains measurement error due to the fact that its level is influenced by the length of project life, the growth rate in gross investment, and the accounting methods adopted by the firm (for example, see Fisher-McGowan)—factors which will be different for different firms in a particular sample. The conditional *IRR* estimate, because they rely on cash flow data, explicit estimates of project lives and investment growth rates, are not influenced by these factors extraneous to profitability assessment. Consequently, the conditional *IRR* estimates are profitability estimates which are free from three specific sources of measurement error which are known to be present in the *ARR*.

### III. The Evidence

#### A. Data Description

In order to examine the nature of the measurement error in the *ARR* in the con-

<sup>6</sup>I am grateful to an anonymous reviewer of a previous version of this paper for the comment that led to the incorporation herein of the "sensitivity" issue.

text of studies of the relationship between firm profitability and firm size, the data to calculate the *ARR*, four conditional *IRRs*, and a measure of firm size was collected. The firms which were the subject of analysis were the manufacturing firms on a COMPUSTAT tape which possessed all the financial statement data required to calculate the values of these variables for each of the five years 1974–78. There were 197 firms which met the data requirements.<sup>7</sup>

The size of each firm (hereafter *TA*) was measured as the average of its Total Assets (net) over the period 1974–78. The *ARR* for each firm for each year was calculated as Net Income before Interest Expense, Extraordinary Items, and Discontinued Operations divided by the average Total Assets (net) for the year. The simple average of a firm's five annual *ARRs* was taken as the *ARR* of the firm for the period 1974–78.

Equation (1) was used to estimate four conditional *IRRs* for each firm in the sample. The estimates were obtained by following the procedures described below. First, a *CRR* for each firm for each year was calculated as cash recoveries divided by the gross investment for the year. Cash recoveries were calculated as the sum of Total Funds from Operations, Interest Expense, Sale of Investments, Sale of Property, Plant, and Equipment, and the Decrease in Current Assets (if it occurred). This calculation of cash recoveries followed that of Ijiri (1978). The calculation of cash recoveries does not directly depend upon the level of or the change in the firm's liabilities or equities because of the desire to disentangle the results of the firm's investment activities from the results of its financing activities. The calculation also does not make a distinction between the short- and long-term investments of the firm. Increases in all assets are treated as investments (rather than as reductions in cash recoveries) and decreases in all assets are associated with cash recoveries (i.e., recoveries associated with a prior investment of funds).

Gross investment for each year was calculated as the average of beginning and ending Total Assets (gross) (See Ijiri, 1978, pp. 345–47; 1980, pp. 55–56). The simple average of a firm's five *CRRs* was defined to be the firm's *CRR* for the period 1974–78. Second, an estimate of the useful life of the projects and of the investment growth rate of each firm was needed in order to convert (via equation (1)) each firm's *CRR* into conditional estimates of its *IRR*. An estimate of the useful life of firm projects was obtained for each firm for each year by dividing the average of its Gross Plant for the year by its Depreciation Expense for the year. The average of these annual estimates was used as the estimate of the life of each firm's projects. An estimate of each firm's growth rate in gross investment over the period 1974–78 was calculated as  $1/5 \log (\text{Gross investment, 1978} / \text{Gross investment, 1974})$ . These steps gave values for *CRR*, *n*, and *g* for each firm in the sample. Finally, these estimated values along with the previously discussed values for the parameter *b* (i.e., *b* = .8, 1.0, 1.1, or a random assignment from (.8, 1.1)) were substituted into equation (1) and produced four conditional *IRR* estimates for each firm in the sample. Table 1 presents some summary statistics for the variables that are used in the remaining analysis of this paper—*ARR*, *IRR*(1), *IRR*(*ran*), and *TA*.

### B. Empirical results

The first step in the data analysis was to determine the properties of the measurement error contained in the *ARR* and to determine if the nature of the estimated properties was sensitive to the assumed level of the firm's cash flow parameter. This determination began with a cross-sectional regression of *ARR* on each conditional *IRR* estimate. Information regarding the cross-sectional regression of *ARR* on *IRR*(1) is presented in Panel A of Table 2 while information about the regression of *ARR* on *IRR*(*ran*) is presented in Panel B of Table 2. In both cases the *ARR* and the conditional *IRR* estimate are significantly and positively related. It is important to note, however, that there is considerable variation in the *ARR* that is not

<sup>7</sup>A computer listing of these firms and their industry affiliation is available from the author upon request.

TABLE 1—SAMPLE SUMMARY STATISTICS: PROFITABILITY MEASURES AND AVERAGE SIZE 1974–78, 197 FIRMS

	ARR	IRR(1) <sup>a</sup>	IRR(ran) <sup>b</sup>	TA

Variable	Estimated Coefficient	Standard Error	t-Score	Significance Level
A: $ARR = \beta_1 IRR(1) + \beta_0 + ME(1)$				
IRR(1)	.545	.047	11.67	.001
Constant	.042	.005	—	—
Correlation (ARR, IRR(1)) = .64				
B: $ARR = \beta_1 IRR(ran) + \beta_0 + ME(ran)$				
IRR(ran)	.374	.045	8.3	.001
Constant	.055	.005	—	—
Correlation (ARR, IRR(ran)) = .51				

explained by the estimated conditional IRRs. In particular, approximately 60 percent (74 percent) of the cross-sectional variation in the ARR is explained by factors other than the profitability of firm projects as measured by IRR(1) (IRR(ran)).

The regressions of ARR on each of the conditional IRRs were used to obtain an estimate of the measurement error in the ARR of each firm. The ARR-based measurement error was calculated as follows:

(3)  $ME_j(.) = ARR_j - [\beta_1 IRR_j(.) - \beta_0]$ ,

where  $ME_j(.)$  = an estimate of the measurement error in the ARR of firm  $j$  ( $j = 1, 2, \dots, 197$ ) given a conditional  $IRR_j(.)$  estimate of firm  $j$  with  $IRR_j(.) = [IRR_j(1),$

$IRR_j(ran)]$ ;  $\beta_1, \beta_0$  = the estimated slope and intercept coefficients from the cross-sectional regression of ARR on  $IRR(.)$ ; and  $ME_j(.)$  represents an estimate of that part of the ARR of firm  $j$  which is influenced by factors other than the conditional  $IRR_j(.)$  of firm  $j$ 's projects. The level of the association between  $ME_j(.)$  and TA will determine whether the ARR does or does not contain systematic measurement error in the context of studies of the relationship between firm profitability and firm size.

Table 3 displays the results of the regressions of  $ME_j(.)$  on firm size (TA). Panel A displays the results given the conditional IRR that assumed a common and level cash flow pattern for the projects of all firms. Panel B displays the results given the conditional IRR

estimate that was based upon a random assignment of a different value to the cash flow pattern parameter of each firm. In both cases, there is a significant ( $\alpha = .05$ ; one-tailed test) positive association between the estimated measurement error in the *ARR* and the size of the firm.

The results depicted in Panels A and B of Table 3 are important for three reasons. First, given that the positive association between the *ARR*-based measurement error and firm size was robust with respect to the four different project cash flow profiles examined, it would be difficult to attribute the systematic nature of the *ARR*-based measurement error to the fact that the cash flow profiles in this paper were assumed rather

than estimated. Second, the observed positive association between  $ME_j(.)$  and *TA* is consistent with the differences in the accounting methods used by large and small firms and the predicted impact of such differences on the reported *ARR*. Consequently, this result can be interpreted as a partial validation of Fisher-McGowan's theoretical model. Third, the fact that the measurement error in the *ARR* in firm-size studies is systematic rather than random means that the tests of association between *ARR* and *TA* are biased rather than weak tests of the association between firm profitability and firm size. The next step in the data analysis was to determine if the strength of the association between  $ME_j(.)$  and *TA* was strong

enough to induce an importantly higher association between firm profitability and firm size when profitability is measured by the *ARR* than when profitability is measured by a conditional *IRR*.

Table 4 presents the results of regressing three measures of firm profitability on firm size. Panels B and C of Table 4 reveal that profitability and size are not significantly related when profitability is measured by *IRR*(1) or *IRR*(ran), respectively. On the other hand, Panel A of Table 4 reveals that profitability and size are significantly ( $\alpha = .025$ , one-tailed test) positively related when profitability is measured by the *ARR*. The results of Tables 3 and 4, taken together, are consistent with the view that it is the nature and the strength of the measurement error in the *ARR*, rather than the correctness of the underlying economic arguments, which accounts for the observed positive association between firm size and firm profitability in studies which have measured profitability by the *ARR*.

#### IV. Summary and Suggestions for Future Research

This paper has relied upon conditional *IRR* estimates to demonstrate that the *ARR* contains systematic—not random—measurement error in the context of studies of the relationship between firm profitability and firm size. The results of this paper suggest two different avenues for future research. The first avenue concerns the determination of the nature of the measurement error in the *ARR* in studies where explanatory variables other than firm size are the subject of analysis. Systematic measurement error is likely to be found in some of these studies because of the dependence of the *ARR* on the accounting methods adopted by firms and the documented systematic association between some economic variables and these accounting methods. For example, Dhaliwal, myself, and Smith found systematic differences in the depreciation methods adopted by management-controlled and owner-controlled firms. Consequently, studies of the relationship between *ARR* and the control status of firms (for example, David

Kamerschen, 1968, and R. Joseph Monsen, J. S. Chiu, and D. E. Cooley, 1968) are predicted to be ones in which the *ARR* will contain systematic rather than random measurement error. On the other hand, the *ARR* is likely to contain random measurement error in some settings because there is only a weak or no association between the explanatory variables of interest and the accounting methods used by firms. For example, there is mixed evidence about whether firms in industries of different sales concentration have systematically different accounting methods (for example, see Hagerman and L. Senbet, 1976, vs. Hagerman and Zmijewski) and there is no evidence to suggest that firms of different advertising intensity have systematically different accounting methods. Consequently, the *ARR* is predicted to have the properties which make it a reasonable *IRR* surrogate in studies of industrial sales concentration and advertising intensity. Preliminary evidence consistent with these predictions is provided in my paper with Moriarty and my paper with Linn and Albrecht. Economists, by following this first avenue of research, will begin to develop a body of evidence which will allow past *ARR*-based studies that are reliable to be conceptually separated from those that are not.

The second avenue for future research arises because the *IRR* estimates relied upon in this paper are conditional on assumed knowledge of the cash flow profiles of firm projects. A broad-based study involving regressions of cash recoveries on a distributed lag of past investment as suggested by Zvi Griliches (see Fisher-McGowan, p. 91, fn. 21) would provide empirical evidence on the cash flow profiles of actual firms. This evidence would provide guidance to analytic work on the relationship between a firm's *CRR* and *IRR* so that future empirical research would be able to rely on more refined *IRR* estimates than those used in the current study.

# Urban Land Prices under Uncertainty

By SHERIDAN TITMAN\*

Land prices in west Los Angeles are among the highest in the United States. Yet, we can observe a number of vacant lots and grossly underutilized land in this area. A good example of this is a parking lot, owned by the University of California-Los Angeles, in an area of Westwood where land has been known to sell for more than \$100 per square foot. The university could probably raise a considerable amount of money by selling two-thirds of the parking lot and constructing a parking structure on the remaining land to satisfy the demand for parking. Although this may be one of the best examples of underutilized land in west Los Angeles, it is by no means the only example. There are many underutilized and vacant urban lots throughout Los Angeles and the rest of the world, held by private investors who presumably wish to maximize their wealth.

The fact that investors choose to keep valuable land vacant or underutilized for prolonged periods of time suggests that the land is more valuable as a potential site for development in the future than it is as an actual site for constructing any particular building at the present time. Hence, in order to understand why certain urban lots remain vacant, we must determine how the land is valued under the two alternatives. Valuing the land as a site for constructing a particular building at the current time is fairly straightforward. It is simply the market value of the building (including the land) minus the lot preparation and construction costs (this is referred to in the real estate literature as residual value). However, valuing the vacant land as a potential building site is not as straightforward since the type of building

that will eventually be built on the land, as well as the future real estate prices, are uncertain.

The model developed in this paper provides a valuation equation for pricing vacant lots of this type. Although the model is very simple, it provides strong intuition about the conditions under which it is rational to postpone building until a future date. Furthermore, the pricing model can be adapted to provide realistic estimates of urban land values in much more complex settings.

The notion that it is often optimal to delay irreversible investment decisions has previously been considered in the environmental economics and capital investments literature.<sup>1</sup> The basic intuition in these papers is that it may be advantageous to wait for additional information before deciding upon the exact specifications of the investment project. While the authors demonstrate that it is often valuable to delay investment, and maintain the option to choose a better investment project in the future, they do not explicitly show how this option affects the value of other related assets in their models.

This paper adapts the methods first used by Fisher Black and Myron Scholes (1973) and Robert Merton (1973), to value options and other derivative securities, to determine explicit values for vacant urban land. The valuation model is particularly close in its approach to the binomial option pricing models of John Cox, Stephen Ross, and Mark Rubinstein (1979), and Richard Rendleman and Brit Bartter (1979). The intuition being that a vacant lot can be viewed as an option to purchase one of a number of different possible buildings at exercise prices that are equal to their respective construction costs.

\*Graduate School of Management, University of California, Los Angeles, CA 90024. I thank Fred Case, Nai-Fu Chen, Margaret Fry, Mark Grinblatt, Frank Mittelbach, and Brett Trueman for helpful comments.

<sup>1</sup>See, for example, John Krutilla (1967), Alex Cukierman (1980), Douglas Greenley, Richard Walsh, and Robert Young, (1981), and Ben Bernanke (1983).

This approach provides a valuation formula that is a function of observable variables and is independent of the investor's preferences.

This valuation technique should be contrasted to the standard textbook approach to valuing vacant land under uncertainty.<sup>2</sup> Richard Ratcliff (1972), for instance, suggests that appraisers determine the most probable future use of the land, appraise the property as of that future time and that use, and then discount this future value to the present. This method ignores the fact that the type of building that will be constructed in the future is generally unknown, and will be determined by real estate prices at that time. The analysis in this paper demonstrates that the amount of uncertainty about the type of building that will be optimal in the future is an important determinant of the value of vacant land. If there is a lot of uncertainty about future real estate prices, then the option to select the type of building in the future is very valuable. This makes the vacant land relatively more valuable and makes the decision to develop the land at the current time relatively less attractive. However, if there is very little uncertainty about future real estate prices, the option to select the appropriate type of building in the future is relatively less valuable. In this case, the decision to develop the land at the current time is relatively more attractive.

My analysis provides more than just a novel method for valuing land under uncertainty. It enables us to address issues, previously unexplored, that pertain to the effect of uncertainty on real estate markets. My results relating to how uncertainty about future real estate prices affect current real estate activities has important policy implications. For example, the analysis suggests that government action intended to stimulate con-

struction activities may actually lead to a decrease in such activities if the extent and duration of the activity is uncertain. The analysis also has policy implications regarding the imposition of height restrictions on buildings. It is shown that the initiation of height restrictions, perhaps for the purpose of limiting growth in an area, may lead to an increase in building activity in the area because of the consequent decrease in uncertainty regarding the optimal height of the buildings, and thus has the immediate affect of increasing the number of building units in an area.

The paper is organized as follows: Section I examines the type of building, characterized by its size, that will be built at a given date if the land is to be developed at that time. Section II presents a simple two-date, two states of nature, model for determining the value of the vacant land for the case where the future price of building units, and hence the size of the building that is to be constructed, is uncertain. A simple numerical example that illustrates this valuation technique is presented in Section III. Section IV presents a comparative static analysis of this valuation model which includes, among other things, an analysis of the effect of uncertainty on vacant land value. Section V examines a model where the current price and rental rate on building units as well as land values are endogenous and Section VI provides a numerical example which illustrates how the valuation technique can be applied to value land with many possible building dates and many possible states of nature corresponding to each date.

### I. The Optimal Building Size

Buildings, in this model, are characterized by their size, or number of units,  $q$ . The cost of constructing a building on a given piece of land,  $C$ , is an increasing and convex function of the number of units, that is,  $dC/dq > 0$  and  $d^2C/dq^2 > 0$ . The rationale for the second assumption is that as the number of floors in a building increases, labor costs per floor increase and the foundation of the building must be stronger. It is also assumed that subsequent to completing a building of

<sup>2</sup>I am unaware of any extant land pricing models that consider uncertainty. However, Donald Shoup (1970), Chapman Findlay and Hugh Howson (1975), and James Markusen and David Scheffman (1978) have examined some of the issues analyzed here within certainty models. Also, René Stulz (1982) suggested that the model he developed for pricing options to purchase one of two risky assets could be applied to price land in some specific cases.

a certain size, it is prohibitively expensive to add additional building units.

Given these assumptions, the building size that maximizes the wealth of a landowner who wishes to construct a building at the present time will satisfy the following maximization problem:

$$(1) \quad \underset{(q)}{\text{Max}} \Pi(p_0) = p_0 q - C(q),$$

where  $p_0$  is the current market price per building unit.

Differentiating (1) with respect to  $q$ , it follows that the solution to this maximization problem is to choose a building size which satisfies the condition,

$$(2) \quad dC/dq = p_0.$$

The building size that satisfies this equality will be denoted  $q^*$ . Given this optimal decision, it follows directly that the value of the land for building at the present time,  $\Pi(p_0)$ , is an increasing and convex function of  $p_0$ . It should be noted that the convexity results because the landowner can change  $q^*$  in response to changes in  $p_0$ .

I will later demonstrate, within a more specialized model, that because of this convexity property, greater uncertainty about the future unit price of buildings increases the current value of vacant land. The basic intuition behind this result can be seen by comparing the expected value of the land for building at date 1, over uncertain realizations of  $\tilde{p}_1$  with the value of the land given a known date 1 price of  $\hat{p}_1 = E(\tilde{p}_1)$ . It follows from Jensen's inequality that

$$(3) \quad E(\Pi(\tilde{p}_1)) > \Pi(E(\tilde{p}_1)).$$

Hence, uncertainty increases the expected future value of the vacant land. This implies that uncertainty causes current vacant land values to increase at least for the case where investors are risk neutral.<sup>3</sup>

<sup>3</sup>For the special cases where  $\tilde{p}_1$  is normally distributed, or where  $C(q)$  is quadratic, the expected future value of land is monotonically increasing in the variance of  $\tilde{p}_1$ .

## II. Valuing Urban Land under Uncertainty

Here I present a simple model for valuing land under uncertainty. Although the model makes no assumptions about investor preferences, other simplifying assumptions are made. The model consists of only two dates, so if the landowner chooses not to build at the present date (date 0), he or she will develop the land at date 1 if  $\pi(p_1) > 0$ . Holding vacant land is assumed to generate no revenues or costs. Uncertainty, in this model, enters in a very simplistic manner. First, the only source of uncertainty pertains to the market price of building units. Per unit construction costs are known and constant. Furthermore,  $\tilde{p}_1$ , the date 1 price of building units takes on one of only two possible values,  $p_h$  and  $p_l$ , where  $p_h > p_l$ . Given that building units can take on only two possible prices on the second date and building costs are constant, it follows that the land at date 1 can take on only two possible values,  $\pi(p_h)$  and  $\pi(p_l)$ . It should be noted that these simplifying assumptions are relaxed considerably in Section VI. It is also assumed that a risk-free asset exists with a return of  $R_f$ . The per unit rental rate,  $R_t$ , is initially assumed to be exogenous; however, this variable is determined endogenously in the model presented in Section V. Finally, it is assumed that markets are perfect in that there are no taxes, no transaction costs, and no short-selling restrictions.<sup>4</sup>

The vacant land can be considered what the finance literature refers to as a contingent or derivative security. Its date 1 value is completely determined by (or derived from)

<sup>4</sup>The assumption of frictionless markets, generally assumed in models of security prices, is considered by some to be less realistic when applied to real estate markets. However, it should be noted that securities represent indirect claims on factories and equipment that are probably much less liquid than real estate. Yet we can price these assets as if they were perfectly liquid because the securities are traded on (almost) frictionless markets. Similarly, a large fraction of real estate is held by publicly traded firms. If the real estate investments of these firms are chosen in a manner consistent with value maximization, then real estate prices will be determined in equilibrium as if markets were really frictionless.

an exogenously priced asset, the date 1 price of building units. In the finance literature, options and other contingent securities are valued by forming a hedge portfolio, consisting of the risk-free asset and the exogenously priced primitive asset, that is perfectly correlated with the contingent security. In the absence of riskless arbitrage, the contingent security must have the same value as this hedge portfolio.

The vacant land can be similarly valued in this model. Since there exist three investments (land, building units, and the risk-free asset) that take on at most two possible values, the returns of the vacant land can be exactly duplicated by a linear combination of the returns of the building units and the risk-free asset. Hence, in the absence of riskless arbitrage, the price of the vacant land can be determined as a function of these investments.

An easy way to solve this pricing problem is to first determine the state prices, (i.e., the cost at date 0 of receiving one dollar in one of the two date 1 states of nature and zero dollars in the other), and then sum the products of these state prices and the land values in the two states of nature. These state prices,  $s_h$  and  $s_l$ , must satisfy the following two equations that express the date 0 price of building units and the price of a discount bond as functions of their date 1 cash flows:

$$(4) \quad p_0 = s_h p_h + s_l p_l + R_f (s_h + s_l)$$

$$(5) \quad 1/(1 + R_f) = s_l + s_h.$$

Solving these equations yields the following state prices for high and low price states of nature, respectively:

$$(6) \quad s_h = \frac{p_0 - (p_l + R_f/1 + R_f)}{p_h - p_l}$$

and

$$(7) \quad s_l = \frac{(p_h + R_f/1 + R_f) - p_0}{p_h - p_l}.$$

Given these state prices, it follows that if no opportunities for riskless arbitrage exists,

the price of vacant land at date 0 must be

$$(8) \quad V = \Pi(p_h) s_h + \Pi(p_l) s_l.$$

If the value of the vacant land, as specified in equation (8), exceeds the profit from building at the present date,  $\Pi(p_0)$ , the wealth-maximizing landowner will choose to have the land remain vacant. Otherwise, he or she will build at date 0 the size building that satisfies equation (2).

### III. A Simple Numerical Example

Consider the example where an investor owns a lot that is suitable for either six or nine condominium units. The per unit construction costs of the building with six and nine units is \$80,000 and \$90,000, respectively. The current market price of the units is \$100,000. The per year rental rate is \$8,000 per unit (net of expenses) and the risk-free rate of interest for the year is 12 percent. If market conditions are favorable next year, the condominiums will sell for \$120,000; if conditions are unfavorable, they will sell for only \$90,000.

Since the marginal cost, per unit, of building nine rather than six units is \$110,000, the investor will build a six-unit building and realize a profit of \$120,000 if he builds at the current time. However, if he chooses to wait one year to build, he will construct a six-unit building if market conditions are unfavorable and realize a total profit of \$60,000, and will build a nine-unit building and realize a total profit of \$270,000 if favorable market conditions prevail. Substituting these numbers into equation (8) yields a current value for this land, if it is to remain vacant until next year, of \$141,071. Since this is greater than the profit that would be realized by building immediately, it is better to keep the land vacant.

If the land sells for less than this amount, investors can earn arbitrage profits by purchasing the land, and hedging the risk by short-selling the condominium units. For example, if the land sold for \$120,000, investors could realize a risk-free gain with no initial investment by purchasing the land, short-selling seven condominium units, and in-

vesting the net proceeds from the transactions in the risk-free asset. The seven condominium units completely hedges the risk from owning the vacant land since the difference between the value of the units in the good and bad states of nature, \$210,000, exactly offsets the difference in land values in the two states. Hence, the above investment yields a risk-free gain of \$23,600. Since such gains cannot exist in equilibrium, investors will bid up the price of the land to its equilibrium value of \$141,071.

#### IV. Comparative Statics

The above numerical example illustrates the effects of the current price of the building units, the interest rate, and the rental rate on the current value of vacant land. Recall that in order to hedge the risk from owning the vacant land, individual building units were sold, with the proceeds invested in the risk-free asset. If the price of the building units increases, the proceeds from the short sale increase, so the vacant land becomes more valuable. Similarly, if the interest rate increases, the income from the risk-free asset increases so the vacant land becomes less valuable. Conversely, if the rental rate increases, the cost of maintaining the short position increases, so the value of the vacant land decreases.

These comparative static results can be shown formally by differentiating equation (8) under the assumption that  $p_h$  and  $p_l$  are fixed:

$$(9a) \quad \partial V / \partial p_0 = \frac{\Pi(p_h) - \Pi(p_l)}{p_h - p_l} > 0,$$

$$(9b) \quad \partial V / \partial R_f = \frac{\Pi(p_h)(p_l + R_f) - \Pi(p_l)(p_h + R_f)}{(p_h - p_l)(1 + R_f)^2} > 0,$$

$$(9c) \quad \partial V / \partial R_t = \frac{\Pi(p_l) - \Pi(p_h)}{(p_h - p_l)(1 + R_f)} < 0.$$

The preceding analysis implicitly assumes that the current price and rental rate on

building units are unaffected by changes in the risk-free rate. Alternatively, we can examine the case where  $R_t$  is constrained to equal  $R_f p_0$ . A change in the risk-free rate accompanied by a proportional change in the rental rate can then be analyzed by substituting  $R_f p_0$  for  $R_t$  in equation (8) to yield

$$(8') \quad V = \Pi(p_h) \left( \frac{p_0 - p_l}{(p_h - p_l)(1 + R_f)} \right) + \Pi(p_l) \left( \frac{p_h - p_0}{(p_h - p_l)(1 + R_f)} \right).$$

It is clear from the above equation that the value of the vacant land decreases if an increase in interest rates is accompanied by a corresponding increase in rental rates.

The valuation technique presented in Section IV above also enables us to analyze the effect of increased uncertainty on land values. This is done by considering the effect of increasing the spread between  $p_h$  and  $p_l$  in such a way that state prices remain constant, and are consistent with both current rental rates and the prices of building units remaining constant. Hence, the effect of uncertainty on land values established here is applicable to cross-sectional comparisons holding current building prices constant.

One can easily verify that if  $p_h$  increases by  $x$  dollars and  $p_l$  decreases by  $xs_h/s_l$  dollars, the state prices remain unchanged. Also, the value  $p_h s_h + p_l s_l = p_0 - R_t / (1 + R_f)$  remains unchanged. This is consistent with, but does not require,  $p_0$  and  $R_t$  to remain unchanged. However, the value of vacant land,

$$(10) \quad V = \Pi(p_h + x)s_h + \Pi(p_l - (xs_h/s_l))s_l,$$

is an increasing function of  $x$ . This can be seen by differentiating  $V$ , in equation (10), with respect to  $x$ :

$$dV/dx = \Pi'(p_h + x)s_h + \Pi'(p_l - (xs_h/s_l))s_h.$$

It follows from the convexity of  $\Pi(p)$  that

$$dV/dx > 0 \quad \text{since}$$

$$\Pi'(p_h + x) > \Pi'(p_l - (xs_h/s_l)).$$

This result indicates that if the amount of uncertainty increases, the value of the vacant land increases, decreasing the relative attractiveness of constructing a building at the current time. Developing the land at the current time becomes less attractive because the increased uncertainty about future prices makes the size of the building that will be optimal at the future date more uncertain, which in turn makes it more likely that the optimal building size at the current time will be suboptimal in the future. If the building size ( $q^*$ ) that will be constructed in the future is known, perhaps because of height restrictions, then the amount of uncertainty about future prices will not enter the decision as to whether to build now or to build in the future. The decision will instead be determined by a comparison between the rental rate and the return from investing the construction expenses in the risk-free asset. This can be seen by comparing the value of the land for constructing a building with  $q^*$  units at the current time period:

$$(11) \quad \Pi = p_0 q^* - C(q^*),$$

with its value as a building site for next period:

$$(12) \quad V = s_h [p_h q^* - C(q^*)] + s_l [p_l q^* - C(q^*)].$$

Substituting equation (7) into (12) yields

$$(13) \quad V = p_0 q^* - R_l q^* (s_h + s_l) - C(q^*) (s_h + s_l),$$

which suggests that the building should be constructed at the present date if and only if,

$$(C(q^*) + R_l q^*) / (1 + R_f) > C(q^*),$$

which simplifies to

$$(14) \quad R_l q^* > R_f C(q^*).$$

Since condition (14) is less restrictive than the condition  $\Pi(p_0) > V$  (for the case where there are no building restrictions), a particular piece of land may be developed at the present date (if height restrictions are imposed), in circumstances under which it would not be developed otherwise. Hence, the imposition of height restrictions can conceivably have the immediate effect of increasing the number of building units in a particular area.

The effects of changes in future building prices, which do lead to changes in current building prices, can also be examined within this model. An increase in  $p_h$ , holding  $p_l$ ,  $s_l$ ,  $s_h$ , and  $R_l$  constant, will increase  $p_0$  by the amount  $s_h$  (see equation (4)), which in turn will increase the profit from developing the land at the current date by the amount

$$(15) \quad d\Pi/dp_h = \Pi'(p_0) s_h.$$

From equation (8), this increase in  $p_h$  leads to an increase in the value of the vacant land of

$$(16) \quad dV/dp_h = \Pi'(p_h) s_h.$$

If  $p_h$  exceeds  $p_0$ ,  $\Pi'(p_h)$  will exceed  $\Pi'(p_0)$  since  $\Pi(\cdot)$  is convex. In this case, an increase in building prices in the good state of nature increases the current value of the vacant land relative to its value if developed. Hence, it becomes less attractive to build at the current date. In the less likely case where the price of building units in the favorable state of nature is lower than the current price, an increase in  $p_h$  makes it more attractive to build at the current date.

Similarly, a decrease in  $p_l$ , holding the other variables constant, decreases current building unit prices by  $s_l$ , which in turn leads to a decrease in the profit from developing the land at the current date by the amount

$$(17) \quad d\Pi/dp_l = \Pi'(p_0) s_l.$$

This decrease in  $p_l$  leads to a corresponding decrease in the vacant land value of

$$(18) \quad dV/dp_l = \Pi'(p_l)s_l.$$

It follows, from the above equations, that a decrease in  $p_l$  will lead to a decrease in the profit from developing the land at the current date that is greater (less) than the corresponding decrease in the value of the vacant land if  $p_0$  exceeds (is less than)  $p_l$ . The above analysis suggests that any increase in the  $p_h - p_l$  spread makes it relatively more valuable to delay developing the land as long as  $p_h > p_0 > p_l$ . This conforms to the basic intuition that increased uncertainty increases the value of having open alternatives. However, this intuition does not necessarily hold when either  $p_0 > p_h$ , or  $p_0 < p_l$ .

#### V. A Simple Examination

Here I present a simple examination of the effect of increased uncertainty on equilibrium prices and building activity. Up to this point, I have not addressed issues relating to the effect of uncertainty on the current prices and rental rates of building units. In order to do this, I must add structure to the model. The following analysis examines a simple economy that consists of  $N$  identical lots that are initially vacant. If, in equilibrium, all the lots are developed at date 0, then there will exist no vacant lots to value. Conversely, if none of the lots are developed, no building units will exist. Hence, it makes sense to restrict the analysis to equilibria in which some, but not all, of the lots are developed at date 0. This suggests that, in equilibrium, the date 0 value of a vacant lot must equal the profit from developing it at that time:

$$(19) \quad V_0 = \Pi(p_0).$$

The demand for building units at date 0 is expressed as a decreasing function of their rental rate:

$$(20) \quad Q = nq^* = f(R_l),$$

where  $Q$ , the number of building units demanded, is equal to the product of  $n$ , the number of lots that are developed in the current period, and  $q^*$ , the number of building units constructed per lot. The function  $f(R_l)$  is assumed to be continuous and differentiable with  $df/dR_l$  less than zero.

Equations (1), (2), (4), (8), (19), and (20), along with the exogenous  $p_l$ ,  $p_h$ , and  $R_f$ , define a well-specified equilibrium.<sup>5</sup> The effect of uncertainty on this equilibrium can be explored in the manner developed in the previous section; by increasing  $p_h$  by  $x$  and decreasing  $p_l$  by  $xs_h/s_l$  so that  $p_0 - (R_l/(1 + R_f))$ ,  $s_h$  and  $s_l$  remain unchanged.

As was shown previously, an increase in uncertainty of this type leads to an increase in  $V$ . This implies that  $\Pi(p_0)$  must increase, which in turn implies that both  $p_0$  and  $q^*$  must increase. Since  $p_0 - (R_l/(1 + R_f))$  remains constant with changes in  $x$ ,  $R_l$  must also increase. From equation (20) we see that  $Q$  decreases with increases in  $R_l$ . Since  $q^*$  increases and  $Q$  decreases, it must be the case that  $n$  decreases. In other words, if uncertainty is increased in a manner that keeps the state prices constant, prices of both land and building units as well as rental rates will increase, a larger portion of the land will remain vacant, but taller buildings will be constructed.

#### VI. Extensions and Practical Applications

Because of tractability considerations, the valuation model developed in Section II was kept simple. The model consisted of only two dates, with only two possible states of nature at the second date, and construction costs were assumed to be fixed. While these assumptions allow us to easily analyze the effects of uncertainty on land prices, they can be relaxed if our only interest is in developing a practical technique for valuing urban land.

<sup>5</sup>Note that the above equations are all continuous and that the variables are all finite and nonnegative. Hence, the existence of this equilibrium follows directly from Brouwer's fixed-point theorem.

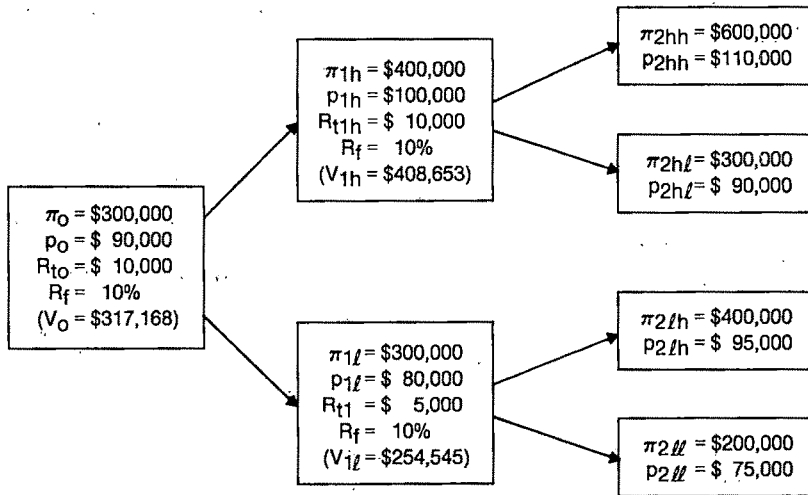

FIGURE 1

The assumption that construction costs are certain can easily be relaxed. The profit from constructing the optimal size building in each date and state of nature can be calculated as long as the construction costs and the per unit price of buildings is specified for each date and state. Substituting these profit levels into equation (8) yields the value of the vacant land.

The pricing model can also be generalized to allow for more than two dates. This can be done by specifying that for each date  $t$  state of nature, two possible date  $t+1$  states of nature can occur. The date 0 land value can then be solved by backwards induction. For each state of nature at the second to last date, the vacant land value is given by equation (8). The larger of this value and the profit from developing the land in each state of nature at this date can then be substituted for  $\Pi$  into equation (8) to calculate the values of vacant land at the third to last date for the different states of nature. By continuing this process, we not only obtain the current value of the vacant land, but also determine at which future dates and states of nature the land is developed. Note also that by making the time periods between dates arbitrarily small and the number of dates arbitrarily large, we can have an arbitrarily large number of states of nature for each future time period. Hence, the assumption of

only two date  $t+1$  future states of nature for each date  $t$  state is not really restrictive.

The following numerical example illustrates this valuation method. It assumes three dates. The profit from developing the land, the per unit building price, and the rental rate is given for each date and state of nature in Figure 1. The value of the vacant land in the two date 1 states of nature are calculated in the manner specified in Section II. Since the value of the vacant land in the favorable state of nature (\$408,635) exceeds the profits from developing the land in this state of nature, the land will remain vacant. However, the value of the land is only \$254,545 in the unfavorable date 1 state of nature. Since this value is less than the profit from developing the land at that date, the land will be developed if the unfavorable state of nature occurs. Substituting the larger of the value of the vacant land and the profit from developing the land in each state of nature for  $\Pi(p)$  in equation (8) yields the date 0 value of the vacant land. Since this value (\$317,168) exceeds the profit from developing the land at date 0, the land will remain vacant at this date.

## VII. Conclusion

The model developed in this paper provides a valuation equation for pricing vacant

lots in urban areas. The analysis demonstrates that the range of possible building sizes provides a valuable option to the owner of vacant land that becomes more valuable as uncertainty about future prices increases. An implication of this relationship between uncertainty and vacant land values is that increased uncertainty leads to a decrease in building activity in the current period.

The relationship between building activity and uncertainty may have important macro implications. An article by Lawrence Summers (1981) and my 1982 article suggest that an increase in anticipated inflation leads to an increase in housing prices, which in turn leads to an increase in construction activity. The analysis presented here suggests that if the government initiates a monetary policy (or any other policy) to stimulate building activity, the policy may actually lead to a decrease in building activity if there is uncertainty about its duration or its effect.

The model also provides insights into the role of real estate speculators who purchase vacant lots, and rather than develop them immediately, choose to keep them vacant for a period of time. By waiting until some future date to build, the speculator is able to construct a building that is most appropriate given economic conditions at that time. Since the exact nature of these economic conditions are unknown at earlier dates, a building constructed earlier will not in general be the optimal size for the future. The decision to build or not build can thus be thought of as weighing the opportunity costs associated with keeping the land vacant against the expected gain from constructing a more appropriate building in the future.

It should also be noted that the framework developed here can easily be extended to analyze other issues relating to real estate pricing under uncertainty. For example, the analysis can easily be augmented to determine the value of houses that may or may not be torn down in the future so that the land can be used to develop large condominium complexes. The framework can also be used to determine when it is optimal to demolish a small building for the purpose of constructing a larger building, and under what conditions it is optimal to renovate an apartment house or convert it to con-

dominiums. One could also use similar techniques to analyze the effect of uncertainty on the optimal durability of buildings.

# A Note on Equity and Efficiency in the Pricing of Local Telephone Services

By EDWARD RENSHAW\*

Since the publication of Bridger Mitchell's article on the "Optimal Pricing of Local Telephone Service" (1978), it has been assumed that social welfare can usually be increased by moving from a flat monthly rate for local calls to a two-part tariff with a price per call that is somewhat in excess of marginal cost. While a fixed monthly charge for local calls can be considered a regressive head tax (A. M. Henderson, 1947), it does not follow that a two-part tariff will resolve the equity problem. In this paper I use a simple diagram and a two-person revenue-maximizing formula to illustrate one of the more important limitations of usage-sensitive pricing.

In the following analysis, it is assumed that there are two types of telephone users. The first type of consumer,  $D_1$ , is assumed to have a *net* demand for calls or message units, represented by the linear equation:

$$(1) \quad P = a - bQ.$$

The second consumer,  $D_2$ , is assumed to have a net *indexed* demand of

$$(2) \quad P = 1.0 - Q.$$

I use the term "net demand" to refer to that portion of the consumers demand curve which lies above the marginal cost of providing local telephone service.<sup>1</sup> In the case of

FIGURE 1. INDIVIDUAL DEMAND FUNCTIONS FOR CALLS OF TWO CONSUMERS WITH DIFFERENT TASTE PARAMETERS BUT THE SAME INCOME

the second consumer, the maximum price that can be obtained for the first call or message unit has been arbitrarily indexed to equal 1.0. The number of calls or message units that will take place when the price per unit of service is set equal to marginal cost ( $MC$ ) has also been indexed to equal 1.0.

In Figure 1,  $a$  in equation (1) is set equal to 1.0, and  $b$  equal to 2.0. Note that both of the demand curves have the same price intercept. At any price less than 1.0, however, the second consumer (who had a greater taste for calling) will make twice as many calls as the first consumer.

The maximum monthly flat rate charge that can be collected from  $D_1$  without causing him or her to disconnect will be equal to the consumers' surplus areas under the demand curve  $D_1$  above  $MC$ , or areas  $(A + B$

\*Department of Economics, State University of New York, Albany, NY 12222.

<sup>1</sup>The short-run marginal cost of a local direct dial call is probably nearly equal to zero in many cases. Whether local telephone companies would be motivated to reduce capacity in the long run in response to a usage price in excess of short-run marginal cost is more conjectural and the subject of considerable controversy. In a mobile society it may not be wise to reduce capacity for a resident with little taste for telephoning, since he or she may move and be replaced by someone with a

higher demand for telephone service. For a provocative discussion of marginal cost, see the article by John Wilson (1983).

+  $C$ ) plus some fixed amount ( $F$ ) that represents that person's option demand and willingness to pay for telephone service just to be able to receive calls that are initiated by others.<sup>2</sup>

Suppose that a monthly customer charge equal to ( $F$ ) plus areas ( $A + B + C$ ) is not enough to recover the fixed costs of maintaining local telephone service. Will it be possible to increase telephone revenues by reducing the monthly customer charge to an amount equal to say ( $F$ ) plus area ( $A$ ) and then charge a price per call,  $P_1$ , that is in excess of marginal cost?

A price equal to  $P_1$  will cause the first consumer to cut back his or her usage from .5 to  $Q_1$  and will reduce the total amount of revenue that can be collected from  $D_1$  by an amount equal to area ( $C$ ). Total revenue will increase, however, if area ( $E$ ), the extra revenue to be obtained from the second consumer,  $D_2$ , is greater than area ( $C$ ).

For the demand structure depicted in Figure 1, total revenue can be increased as long as  $P_1$  is less than .25. We can verify this conclusion in a more general way by noting that the total net revenue in excess of marginal cost can be calculated using the following formula:

$$(3) \quad TR = 2F_1 + P_1Q_1 + P_1Q_2 \\ + 2(a - P_1)Q_1(\frac{1}{2}).$$

The expressions  $P_1Q_1$  and  $P_1Q_2$  represent the net usage sensitive revenues to be obtained from  $D_1$  and  $D_2$  when the per unit charge in excess of marginal cost is set equal to  $P_1$ . The expression  $(a - P_1)Q_1(\frac{1}{2})$  is the consumers' surplus area ( $A$ ). This area plus  $F_1$  represent the maximum customer charge that can be collected from  $D_1$  without causing the consumer to go without telephone service. Both of these customer charge elements are multiplied by two to give us the total amount of flat rate revenue to be obtained from  $D_1$  and  $D_2$ .

Equation (3) provides a general definition of the net revenue that will be available to

compensate for fixed costs and is not related in a very specific way to our assumed demand equations.

When equations (1) and (2) are solved from  $Q_1$  and  $Q_2$  and the resulting expressions are substituted into (3), we obtain a more useful definition of the total revenue to be expected in conjunction with a two-part tariff:

$$(4) \quad TR = 2F_1 + (1 - (a/b))P_1 \\ - P^2 + (a^2/b).$$

Taking the derivative of this revenue function with respect to  $P_1$  and setting the resulting expression equal to zero allows one to solve for the usage sensitive price,  $P_1^*$ , which maximizes net telephone revenue

$$(5) \quad P_1^* = \frac{1}{2} - (a/2b).$$

In constructing Figure 1 it was assumed that  $a = 1.0$ , and that  $b = 2.0$ . When these values are substituted into equation (5), we can show that  $P_1^* = .25$ . If both the  $b$  and  $a$  values in equations (1) and (5) were set equal to 1.0, on the other hand, both consumers would have identical demand curves for local calls and the revenue-maximizing price in excess of marginal cost would be  $P_1^* = 0$ . With,  $a = 1.0$ , we can conclude that the higher the  $b$  value, other things equal, the greater the taste differential, and the greater the revenue maximizing price in excess of marginal cost.

Let us now consider a case where  $a$  and  $b$  in equation (1) are both set equal to .5. (See Figure 2.) The maximum customer charge that can be imposed in this case without causing  $D_1$  to disconnect is the same as in Figure 1 if we assume that there is no difference in  $F_1$ , which represents option demand and a willingness to pay for a telephone connection just to be able to receive calls that are initiated by others.

When  $a = b$ , however, one can use equation (5) to quickly discover that a two-part tariff in excess of marginal usage cost will not increase telephone revenue in the two-person or two-group case where  $D_1$  and  $D_2$  type of demanders are equally numerous.

<sup>2</sup>For a more detailed discussion of the demand for telephone service, see the discussion by Lester Taylor (1980).

FIGURE 2. INDIVIDUAL DEMAND FUNCTIONS FOR CALLS OF TWO CONSUMERS WITH THE SAME TASTE PARAMETERS BUT DIFFERENT INCOMES

This is a rather startling conclusion that can easily be verified in connection with Figure 2 by noting that if a two-part tariff is to raise more net revenue than a flat rate tariff equal to  $F1$  plus areas  $(A + B + C + G)$ , area  $(E)$  will have to be greater than the consumers' surplus loss areas for both consumers,  $(C + G)$  and  $(G)$ .

In his path-breaking article, Mitchell established the precedent of assuming that persons with similar tastes for telephone service and different incomes will have demand curves with similar call intercepts and different price intercepts.<sup>3</sup> To the extent that this characterization is correct, we can conclude that a two-part tariff will not be successful at equalizing the distribution of effective purchasing power and keeping low-income households connected to the telephone network in an era of deregulation and reduced cross subsidization of local telephone service from fancy equipment rentals and long distance communication.

It follows—if one believes that there are external benefits in having most low-income households connected to the telephone sys-

<sup>3</sup> Mitchell's further assumption that there is quite a bit of income variation as well as taste variation no doubt helps to explain why his optimal prices for local telephone service were not very much in excess of his assumed marginal cost.

tem—that serious consideration should be given to other alternatives for furthering the goal of universal service such as well targeted subsidies or rebates to low-income households and geographical price discrimination which would require persons in high-income neighborhoods to pay more for basic telephone service than persons living in low-income neighborhoods.<sup>4</sup>

Census data indicate, in any event, that a considerable part of the variation in local telephone connections can be explained on the basis of income differences. In Nassau County, New York, where the median household income was \$26,091 in 1980, less than 2 percent of the surveyed households were without a telephone. In the not very distant Bronx, on the other hand, where median household income was only \$10,947, more than 17 percent of the households were without a telephone. The best predictor of the proportion of households without a telephone for New York's 62 counties, however, is not median income but the proportion of households below the poverty line.<sup>5</sup>

<sup>4</sup> Geographical price discrimination on the basis of income is somewhat analogous to financing part of the fixed costs of local telephone service with a property tax. In many instances it can be defended on the basis of extra costs of providing telephone service in less thickly settled affluent areas.

<sup>5</sup> The  $r^2$  for the proportion of households below the poverty line is .747 and can be compared to  $r^2$ 's of .554 for median family income and .429 for mean income.

# Women, Work, and Divorce

By WILLIAM SANDER\*

An upward trend in the divorce rate in the U.S. has been attributed to an increase in the earning ability of women (Gary Becker et al., 1977, and Becker, 1981). The reasoning for the increase in marital instability is that high-wage (quality) women "gain less from marriage than other women do because higher earnings reduce the demand for children and the advantages of the sexual division of labor in marriage" (Becker, p. 231).

To some extent, an increase in the earning ability of women is a consequence of a higher divorce rate (Becker). That is, divorced women tend to invest more in work experience and thus command a higher wage.

The economic explanation for a higher divorce rate has been questioned by some (for example, Mark Blaug, 1980) on the grounds that changes in the family structure over time reflect changes in tastes rather than exogenously determined economic effects. That is, investments in work by women reflect, perhaps, an increase in a taste for work and a decrease in a taste for marriage.

In this paper, I present evidence that adds support to the economic approach to divorce. I will show that the divorce rate is significantly and substantially affected by the earning ability of women in market work. Data will be drawn from the U.S. farm sector. After a brief overview of the economic theory of divorce and its relevance to the farm sector, data sources and regression specifications will be discussed.

## I. Theory

A complete treatment of the economic theory of divorce is beyond the scope of this

paper (see Becker et al., and Becker). The most important aspect of the theory, though, is that high-wage women gain less from marriage relative to other women because the gains from specialization within marriage (the wife in household work and the husband in market work) are less. Since high-wage women tend to marry high-wage men, the costs of low-level specialization within the household are at least partly offset by the benefits to women of a high-wage husband. Thus, the net effect would seemingly be ambiguous.

Perhaps more importantly, the shadow price of divorce is less for high-wage women. The reason for this is simply that the marginal economic value of a loss in husband's income is less for a high-wage wife. That is, an increase in the earning ability of women enables them to leave an unhappy marriage and either remain divorced or remarry.

An increase in the male wage should have a positive effect on the gains from marriage because high-wage men tend to attract high-wage wives. For this reason, the independent effect of the male wage on the divorce rate has been shown to be negative.

With respect to the farm sector, the farm divorce rate has been substantially below the urban and rural nonfarm divorce rates (Table 1). In addition, the percent of farm and rural nonfarm men who have been divorced exceeds the rate for farm and rural nonfarm women. On the other hand, there are more divorced women living in urban areas than men. This probably reflects the economic attractiveness of urban areas for divorced women relative to divorced men. That is, divorced women would tend to gain more from migration relative to divorced men because the latter would already tend to be located where their earning ability was relatively high.

The economic theory of divorce indicates that farm families should experience less marital instability than their nonfarm counterparts. Two important reasons for this are that farm wives specialize more in household

(including on-farm) work and less in off-farm market work relative to their nonfarm counterparts. In 1979, 44 percent of farm women were labor force participants. About one-third of these were counted in the labor force via their farm work, while two-thirds were in the labor force via off-farm market work (U.S. Department of Labor, 1980, and Howard Hayghe, 1981). About half of their nonfarm counterparts were in the labor force at this time.

Farm women are more specialized in farm work than the labor force participation statistics indicate. A recent national survey of farm women indicates that most farm women participate in some farm tasks (National Opinion Research Center, 1980). Thus, there is a greater sexual division of labor in the farm household relative to the nonfarm household. It should follow that this increases the gains from marriage for farm wives relative to other wives, to the extent that specialization appreciably affects the gains from marriage.

The earning ability of farm men has increased over time. T. W. Schultz<sup>1</sup> estimates that the average value of the farmer's time is now about the same as the average value of time in the nonfarm sector. I would note that this should be particularly true regarding comparisons of the farm and rural nonfarm sectors. That is, farmers in a state have about the same earning ability as their rural nonfarm counterparts because the two sectors are highly integrated. Therefore, the differential in the earning ability between farm and

nonfarm men cannot be drawn upon to explain a low farm divorce rate. It will be demonstrated that the relatively low level of specialization by farm women in market work explains a substantial part of the farm-rural nonfarm divorce gap.

## II. Data and Specifications

The male farm divorce rate (percent ever been divorced) will be estimated below. The male rate rather than the female rate will be used because it better reflects the real farm rate. As noted above, divorced farm women probably migrate at a higher rate from agriculture than divorced farm men. There is no evidence available regarding migration of divorced farm men from farming.

The key variables that would affect the gains from marriage and, accordingly, the costs of divorce are the husband's wage and the value of the wife's time in household (including on-farm) and market work. In addition, it has been shown that religion has a significant and substantial effect on the cost of divorce.

Data are not available to estimate the independent effects of these variables. However, useful proxies are available that enable one to explain a good part of the pattern in the farm divorce rate. Since the farm and rural nonfarm economies are highly integrated, particularly at the state level, the rural nonfarm divorce rate should pick up the net effect of many of the determinants of the farm divorce rate in a state. In particular, it should pick up the effects of the earning ability of farm men, the level of schooling in the farm sector, and variables that affect the cost of divorce such as religion. To some extent, the correlation coefficients between farm and rural nonfarm average family income in 1970 (.95) and farm and rural nonfarm schooling (.93) indicate the former. No data are available on religion at the substate level.

Since it is not unrealistic to assume that the farm and rural nonfarm economies are highly integrated in a state, it should be expected that the correlation coefficient between the farm and rural nonfarm divorce rate should be high, as well. It was .91 for farm and rural nonfarm men in 1970.

<sup>1</sup>Personal communication, 1984.

However, there is some variability in the difference between the average farm and rural nonfarm divorce rate for men by state. In 1970, the standard deviation for this difference was 2.1. The mean difference was 5.7 in 1970 (see Table 1).

I believe that the difference and the variability in the difference between the farm and rural nonfarm divorce rates for men is primarily a product of differences in the earning ability of farm wives in market work relative to rural nonfarm wives. This difference is indicated to some extent by the relatively low correlation coefficient between the labor force participation rate for farm women and rural nonfarm women. (.55 in 1970). It is important to note that farm women had about the same quantity of schooling as their rural nonfarm counterparts in 1970, although urban women had more schooling. Thus, the level of schooling of farm wives is not the reason for their relatively low level of participation in off-farm market work. That is, the reason that farm women do not acquire market-specific capital relative to their rural nonfarm counterparts is not a product of less schooling.

Although many factors affect labor force participation rates, with state-level data population density was found to be the only significant determinant of the labor force participation rate for farm women and will be used in regressions to reflect this. This should be expected since most farm women are labor force participants via off-farm market work and since the distance to an off-farm job would tend to be less in more densely populated states. That is, the effective off-farm wage rate would tend to be higher for farm women in more densely populated states because location is a key determinant of the acquisition of market-specific capital by farm women. Population density is an interesting measure of the economic value of a woman's time in market work since it is highly exogenous. That is, density is not a consequence of a high divorce rate for farm men in a state.

In addition, the farm-rural nonfarm divorce rate differential could be related to the greater sexual division of labor within the farm household. That is, the gains from marriage might be higher for farm wives if they

TABLE 2—SUMMARY STATISTICS FOR DATA SET, 1970

<sup>c</sup>People in one square mile.

had acquired more marital-specific capital relative to their rural nonfarm counterparts. Without a doubt, farm wives acquired relatively more specific capital. Whether this has a significant effect upon the gains from marriage remains an empirical issue. Farm assets are undoubtedly related to the acquisition of specific capital by wives and will be used in my farm divorce estimates below. Farm assets may also partly reflect the wealth (gains from marriage) that farm wives acquire upon entry into marriage. Thus, farm assets may reflect gains acquired via wealth and specialization.

To sum up, the explanatory variables that will be used to explain variations in the percent of farm men in a state who were known to have been divorced at some time are the rural nonfarm divorce rate for men, farm assets, and population density. In addition, the labor force participation rate for farm women will be added in some regressions to show its effect. As noted above, this variable is a more biased measure of the value of a wife's time in work. Summary statistics are presented in Table 2.

### III. Results

The results of ordinary least squares (OLS) estimates of the "farm divorce rate" (Table 3) are as follows. The rural nonfarm divorce rate had a highly significant and substantial positive effect on the farm divorce rate as one would expect. That is, the rural nonfarm divorce rate is correlated with the farm divorce rate at the state level because some of the determinants of divorce are correlated at

TABLE 3—OLS ESTIMATES OF THE FARM DIVORCE RATES, 1970

	(1)	(2)	(3)	(4)
Population Density	.003 <sup>a</sup> (3.3)	.004 <sup>a</sup> (4.3)	.004 <sup>a</sup> (4.2)

<sup>a</sup>significant at the 5 percent level.

the rural nonfarm and farm levels, as well. Farm assets had a negative sign as would be expected; however, the coefficient was not statistically significant. Population density had a significant positive effect. If population density entered the equation, the labor force participation variable for farm women had a positive sign although it was not significant. This variable was shown to have a significantly positive effect if population density was excluded in the regression. In preliminary work with the data, I could not show that any other variable had a statistically significant effect on the farm-rural nonfarm divorce differential, or any significant effect on my results.

My results provide support for the hypothesis that the divorce rate is positively related to the earning ability of women in market work. In addition, if the regression coefficient for density takes the value of .004 the elasticity at means of density and the divorce rate is .07. This implies that if density took on the value of the most densely populated state, it would increase the farm divorce rate by 40 percent over its mean value. Finally, I regressed the difference between the rural nonfarm divorce rate (for men) and the farm divorce rate (state-level data) on density and average farm assets. The result was:

$$\text{Divorce Differential} = 4.8 + .01 \text{ Assets} - .005 \text{ Density.}$$

(3.9)                      (5.0)

The adjusted  $R^2$  was .47 (*t*-statistics are shown in parentheses). In this regression, I show that an increase in farm assets increases the difference between the rural nonfarm and farm divorce rates. This is the expected result since the gains from marriage should be higher on larger farms. An increase in population density reduces the difference which is consistent with the results in Table 3.

#### IV. Conclusions

It has been shown that an exogenous increase in the earning ability of women substantially increases the divorce rate. That is, in states where farm women have a higher incentive to acquire market specific capital, it becomes more likely that at some time they will become divorced.

The hypothesis that population density affects the farm-rural nonfarm divorce differential via the incentive to invest in market work seems to follow the data. In 1970, the difference between the rural nonfarm and farm divorce rates (percent ever divorced) was the greatest in three sparsely populated states—Nevada, Wyoming, and Arizona. The difference was minimized in three densely populated states—New Jersey, Connecticut, and Massachusetts.

The results regarding the effect of farm assets on the gains from marriage were less illuminating. In estimating the farm divorce rate, farm assets did not seem to be consequential. However, assets did seem to increase the farm-rural nonfarm divorce differential. Thus, less can be said of the effect of assets on the gains from marriage.

However, the divorce rate differential tended to be relatively high in the North Central states where farm assets tend to be high. Included in this group are Illinois, Indiana, Ohio, and Michigan. In these states, the opportunity cost of investments in market work experience by farm wives tend to be high because of the relatively high value of the farm wife's time in on-farm work.

# Money, Anticipated Changes, and Policy Effectiveness

By RICHARD G. SHEEHAN\*

The Lucas-Sargent-Wallace (L-S-W) proposition states that expected policy changes have no influence on real economic variables even in the short run. (See Robert Lucas, 1972, and Thomas Sargent and Neil Wallace, 1975.) One form of empirical test of the L-S-W proposition (the neutrality proposition) began with Robert Barro's (1977; 1978) seminal articles supporting the neutrality proposition. However, more recent papers, including those by David Small (1979), John Makin (1982), and Frederic Mishkin (1982a, b) have reexamined the relationships between anticipated and unanticipated money vs. output, unemployment, and inflation, and have found evidence suggesting that anticipated monetary changes do have real effects. All of the above-cited studies use expectations procedures which estimate, for example, a money growth equation over the entire period under consideration.<sup>1</sup> However, this approach assumes that when expectations are being formed at the beginning of the period, economic agents have the relevant information for the entire period. In this note I reexamine the impact of expected vs. unexpected monetary changes focusing on the informational restrictions actually

faced by economic agents when formulating expectations.

The structure of the model used here is similar to the models of Barro and Mishkin. A measure of real output is assumed to be a function of a policy variable and a vector of predetermined variables. The policy variable can be decomposed into anticipated and unanticipated components. Algebraically:

$$(1) \quad \dot{y}_t = \alpha_1 Z_{1t} + \beta_1 (\dot{m}_t - {}_{t-1}\dot{m}_t) + \delta_1 \dot{m}_t + \varepsilon_{1t}$$

$$(2) \quad \dot{m}_t = \alpha_2 Z_{2t} + \varepsilon_{2t}$$

$$(3) \quad \Sigma = E((\varepsilon_{1t} \varepsilon_{2t})' (\varepsilon_{1t} \varepsilon_{2t})) = \begin{bmatrix} \sigma_1^2 & 0 \\ 0 & \sigma_2^2 \end{bmatrix}$$

where  $\dot{y}$  is the rate of change in a measure of real output,  $Z_1$  and  $Z_2$  are vectors of predetermined variables,  $\dot{m}_t$  is the actual rate of change in a policy variable such as the money supply, and  ${}_{t-1}\dot{m}_t$  refers to the expected rate of change of the policy variable at time  $t$ , conditional on the information available at time  $t-1$ . The  $\varepsilon_{1t}$  and  $\varepsilon_{2t}$  are serially uncorrelated normally distributed error terms, distributed as  $\eta(0, \sigma_1^2)$  and  $\eta(0, \sigma_2^2)$ , respectively. It is further assumed they are contemporaneously independent. Assuming economic agents know the model and form econometrically rational expectations, then

$$(4) \quad {}_{t-1}\dot{m}_t = \alpha_{2t-1} Z_{2t}$$

It is further assumed that economic agents have limited information. For example, economic agents in 1964:1 only have the data actually published before 1964:1. A data revision in, say, 1968:2 for the money stock in 1963:4 does not become available until 1968:3. Each period new data becomes available and any old data may be revised. Both changes may be important when generating expectations. Not only may the estimated

Any errors remaining are, of course, entirely my responsibility. The views and opinions expressed herein are solely my own and do not necessarily represent those of the Federal Reserve Bank of St. Louis or the Federal Reserve System.

<sup>1</sup>Barro (1977) states that he also considered money growth expectations based solely on prior observations but found little change from his reported results. Steven Sheffrin (1979), using an ARIMA model, and Jacob Grossman (1979), using weighted least squares, also add data period by period. However, all three of these studies apparently use the most recent data with all revisions and not the data actually available to economic agents at some earlier point in time.

money growth equation change from period to period, the data used to estimate that equation may also change from period to period. Monetary surprises may occur because of random fluctuations, exogenous shocks, changes in the monetary authority's behavior, or data revisions.

Alternate money forecasting equations are used to test the sensitivity of the results to the method for determining expectations. The forecasting equations differ partly in the choice of included variables. Following Barro, the equation (2) is viewed as a reaction function where monetary changes depend in part on what macro variable the monetary authorities are attempting to control. Algebraically equation (2) can be rewritten as

$$(5) \quad \dot{m}_t = \alpha_3 Z_{3t} + \beta_3 (\dot{X}_{t-1} - \dot{X}_{t-2}) + \varepsilon_{3t},$$

which implies that monetary authorities are attempting to control the expected rate of change of a goal variable  $X$ . Equation (5) is repeatedly reestimated each time using one additional period of data together with any data revisions made in the previous quarter. Anticipated and unanticipated monetary changes are obtained by sequentially forecasting money growth one period ahead using the reestimated equation (5). This procedure is in keeping with the process of letting economic agents revise their estimated forecasting equations only as data actually become available.<sup>2</sup>

<sup>2</sup>Some assumptions must be made concerning when the forecast for a quarter is made and what information is then available. These assumptions are, necessarily, somewhat arbitrary. We assume that economic agents when forecasting, say, 1964:1 have information available in issues of *Business Conditions Digest* up to and including November 1963. Similarly, when forecasting 1964:2 values, economic agents have information from issues of *BCD* prior to and including February 1963. Information is likewise limited throughout the sample. This approach assumes that data revisions at all times have a zero expected mean. If the mean is not zero, then economic agents would anticipate some revision and would incorporate that in their forecasts. The anticipated data revision would then be of concern.

The money forecasting equations are estimated using *OLS* with the dependent specified as the difference in the log of the money stock ( $M1$ ). The equations include as independent variables a constant, a time trend, quarterly dummy variables, eight lags of the dependent variable, and eight lags (of the difference in the log) of either the unemployment rate (to generate  $ME1$ ), the *GNP* deflator (for  $ME2$ ), or nominal *GNP* (for  $ME3$ ). The former is included to facilitate comparison with Barro's original studies, while the latter two were included to allow monetary policymakers to target variables over which they should have some control even under the neutrality proposition. A fourth expectations series ( $ME4$ ) is generated using Jacob Grossman's method of weighted least squares. It includes lagged nominal *GNP* as a dependent variable, and uses the most recent forty observations available at a particular point in time.<sup>3</sup> The first four expectations series on a period-by-period basis reestimate money growth, forecast one period ahead, and use that forecast to generate expected and unexpected changes during the period for which the equation was estimated. A final expectations series ( $ME5$ ) is generated using Barro's basic approach. Anticipated money is estimated using the data available only at the end of the period with the unemployment rate as an explanatory variable.

"Second-stage" equations for real output, the unemployment rate, and the inflation rate are then estimated. These equations include (for the vector  $Z_1$ ) a constant, a time trend, seasonal dummy variables, and eight lags of the dependent variables. Fourth-order polynomial distributed lags (*PDL*) are used for expected ( $\dot{m}^e$ ) and/or unexpected ( $\dot{m}^u$ ) differences in the log of the money stock. The *PDL* specification is chosen, following Mishkin, because it allows long lags on the

<sup>3</sup>Economic agents may rationally believe more recent observations are more important in ascertaining future values. However, any attempt to weight recent observations more heavily would appear to face an insurmountable obstacle in generating a nonarbitrary set of weights. The weights used here are the same as those of Grossman.

<sup>c</sup>Significant at the 90 percent level

independent variable while conserving degrees of freedom. Following Mishkin, both short- and long-lag specifications of the *PDL* are used, the short-lag specifications including eight lags and the long-lag results including twenty lags.<sup>4</sup> Comparing the log-likelihood ratios when the monetary changes are included vs. excluded allows us to test whether the coefficients on either set of terms should be constrained to equal zero. The test statistic is 2 (log likelihood of included—log likelihood of excluded) which is distributed  $\chi^2$  with degrees of freedom equal to the number of zero restrictions. (Since I use fourth-order *PDLs* for both the  $\dot{m}$  and  $\dot{m}e$  terms, the number of zero restrictions is four per constrained series.) Table 1 presents the log-likelihood comparisons for all second-stage equations with real output, the unem-

ployment rate, and inflation as the dependent variables.<sup>5</sup>

Table 1 presents  $\chi^2$  statistics testing the joint significance of all anticipated or unanticipated money changes using alternate specifications of the money reaction function. The short- and long-lag results in Table 1 are unanimous in their support for the contention that unanticipated policy changes have a significant impact on real output, the unemployment rate, and inflation. However, there are considerable differences in the anticipated change variables. In the short-lag equations, most limited information procedures (*ME1*–*ME3*) suggest that expected money changes influence real output but not the unemployment rate or inflation. The weighted least squares approach (*ME4*) indicates expected policy changes influence all

<sup>4</sup>These lag structures are employed simply to facilitate comparison of these results with those of Mishkin. No attempt was made to search for the "preferred" *PDL* specification.

<sup>5</sup>The money forecasting equations are originally estimated from 1954:1 to 1965:4 and are updated through 1981:3. The second-stage equations are then estimated from 1966:1 to 1981:4.

variables. By contrast, Barro's approach (*ME5*) indicates expected policy changes only influence inflation—a result consistent both with Barro's original conclusion and with the neutrality proposition. Only *ME5* with its extreme informational availability assumption is consistent with the neutrality proposition. The results for *ME5* are also consistent with the hypothesis that the expectations are "too good."<sup>6</sup>

The long-lag results also generally provide little comfort for proponents of the neutrality proposition. When the economic agents are restricted in the information to which they have access, then the long-lag results are unanimous in their declaration that expected policy changes influence measures of real economic activity as well as prices. Only in the extreme information case (*ME5*) is the neutrality proposition even partially supported with the conclusion that expected monetary changes do not influence the unemployment rate but do influence prices (and real output).

Table 2 presents the estimated coefficients on *me* and *mu* for one specification of the reaction function, *ME3*. This specification is chosen because it assumes that information is gradually made available to economic agents, because it assumes that economic agents believe that the Federal Reserve targets a variable which the neutrality proposition states it can influence (inflation), because it imposes no a priori weights on prior information used, and because it generally yields the highest log-likelihood ratios. The coefficients suggest, not surprisingly, that both expected and unexpected money changes will initially increase real output and lower the unemployment rate although those changes are largely offset in the long run. The results also suggest that anticipated

changes in the money stock may have even larger short-run impacts than unanticipated changes. The estimated coefficients also suggest that it will take in the vicinity of one year for the inflationary impact on monetary policy to begin to be felt. Finally, it should be noted that the sum of the estimated coefficients on both expected and unexpected money changes are significantly different from one—the value predicted by the neutrality proposition.

The results presented here strongly suggest that the neutrality proposition does not hold in the short run. Anticipated and unanticipated monetary changes both have impacts on real economic variables as well as prices when information is only gradually made available to economic agents. As has been pointed out by Alan Blinder and Robert Gordon in their discussion immediately following Barro and Mark Rush's paper (1980), the neutrality proposition depends primarily on the assumption of flexible prices. Thus these results indirectly suggest prices are not completely flexible in the short run.<sup>7</sup>

My results also suggest that the decision to accept or reject the neutrality proposition is sensitive to the technique used to generate expectations. Specifically, making extreme informational assumptions about the availability of data would make one more likely to accept the neutrality proposition. By contrast, when data is only gradually revealed to economic agents and those agents gradually revise their forecasting procedure, then anticipated monetary variations are no longer neutral in the short run.

<sup>6</sup>Makin has pointed out that if the neutrality hypothesis is true and if some unanticipated policy changes are erroneously labeled anticipated, then the coefficients on the anticipated changes would be biased away from zero. Thus incorrect modeling of expectations could lead to a false rejection on the neutrality proposition. The *ME5* results for  $\beta = 0$  given  $\alpha = 0$  strongly suggest this possibility.

<sup>7</sup>The neutrality proposition also depends on rational expectations. I do not attempt to test the hypothesis that expectations are formed rationally. It is taken as a maintained hypothesis. Given that expectations are in general unobservable, with differences possible between individuals, and potentially subject to nearly continuous change, I do not feel the assumption of rational expectations can be meaningfully tested in the context of this paper. Of course, the results here, as all previous results rejecting the neutrality proposition, can be alternately interpreted as rejection of the hypothesis that the expectations formation process is accurately modeled. However, that interpretation is made somewhat more difficult by the agreement of the alternate forms *ME1*–*ME4*.

The results presented here are not without problems. The procedure used to generate expectations is still far from perfect. There remains a potential aggregation problem with different economic agents potentially having systematically different expectations. I am attempting to approximate an aggregate un-

observable variable. In addition, expectations are continually revised and updated based on new information, while in this study I can only attempt to model expectations at a particular point in time. Finally, economic agents may also have more information than it has been assumed they have. For example,

expectations are also undoubtedly based in part on variables not considered here, such as elections, wars, and rumors.

# Inflation and Reputation

By DAVID BACKUS AND JOHN DRIFFILL\*

Economists have speculated for years about the source of the apparent inflationary bias of market economies. In the 1960's the Phillips curve supplied part of an explanation: with a stable tradeoff between inflation and output, governments might reasonably choose a positive rate of inflation, even if they find inflation distasteful, in order to raise output.

Natural rate theories changed all that. If the government can only raise output with surprise inflation, then systematic expansionary policy will generate inflation but fail to raise output. If a stable price level is desirable, the only sensible policy is zero inflation. The question then is why government policy has tolerated persistent high rates of inflation over the past decade or so.

One answer is that zero inflation is not a credible policy if the government is known to care about output. This has arisen as "dynamic inconsistency" in Finn Kydland and Edward Prescott (1977) and as inferiority of Nash solutions in Robert Barro and David Gordon (1983a,b), but generally reflects the fact that noncooperative equilibria need not be Pareto optimal.

Another line of argument runs that governments, exploiting the short memories of voters, overheat the economy prior to elections. (William Nordhaus, 1975, provides such a model of "political business cycles" and Gerald Kramer, 1971, and Ray Fair, 1978, report evidence that voters seem to be shortsighted; Henry Chappell, 1983, gives a conflicting view.) This mechanism, however, only leads to an inflationary bias if the Phillips curve is nonlinear, so that high output

raises inflation by more than low output reduces it.

In the following sections we extend the work of Barro and Gordon to a situation in which the public is uncertain about the preferences of the government: in particular, whether it cares about unemployment and output. Thus, when the government announces its intention to fight inflation regardless of the output cost, the public is uncertain whether this is in fact the case, or whether it is simply an attempt to manipulate their expectations. This analysis of reputation, based on David Kreps and Robert Wilson (1982b), provides a useful formalization of the credibility problem faced by macroeconomic policymakers, and stressed repeatedly by William Fellner (1982).

One feature of the model is that tight macroeconomic policy aimed at eliminating inflation will reduce output below the natural rate if the public thinks the government may inflate. Peter Howitt (1982) makes a similar point without elaborating on the source of the public's skepticism. The critical element in our model is the public's lack of information about the government: even if the government is serious about combating inflation, the public cannot know this with certainty. Completely credible noninflationary policy is generally not possible.

A second feature of the analysis is that government policy is dynamically consistent: in equilibrium the government always finds it optimal to stick to its initial plan. By treating policy as a dynamic game and applying Kreps and Wilson's (1982a) notion of sequential equilibrium, we avoid the "inconsistency of optimal plans" that has plagued studies that view policy as an optimization problem.

At the same time we explain the political business cycle without recourse to voter naivete. Even governments that care about employment will tend, at the start of their terms of office, to act as if they do not in order to keep alive in the mind of the public

\*Departments of Economics, Queen's University, Kingston, K7L 3N6 Canada, and University of Southampton, Southampton, S09 5NH England, respectively. Backus thanks the SSHRC of Canada for financial support.

the possibility that they will fight inflation at all costs. Of course, such governments will always inflate near the end of their terms in an attempt to raise output. What is more, it will work: output rises (probabilistically) as long as the government still has a reputation for toughness. The public acts rationally throughout: it simply does not know what the government plans to do.

These ideas are developed in the rest of the paper. Section I reviews the Barro-Gordon model. The analysis of Kreps and Wilson is applied to this model in Section II. A numerical example and discussion follow. The final section contains general remarks about the strengths and limitations of the analysis.

### I. The Barro-Gordon Analysis

Barro and Gordon (1983b) characterize macroeconomic policy as a game. Output is determined by a Phillips curve with the natural rate property:

$$y = y_n + (x - x^e),$$

where  $y$  is output,  $y_n$  is the natural rate, and  $x$  and  $x^e$  are actual and expected inflation. The government likes output and dislikes inflation, which we may formalize with the one-period payoff function

$$\begin{aligned} (1) \quad u_g(x, x^e) &= -\frac{1}{2}ax^2 + b(y - y_n) \\ &= -\frac{1}{2}ax^2 + b(x - x^e). \end{aligned}$$

The public, on the other hand, resists being fooled; that is, they maximize

$$(2) \quad u_p(x, x^e) = -(x - x^e)^2.$$

As Barro and Gordon (1983a) argue, these payoffs are consistent with the government and the public having identical preferences. If the natural rate of unemployment is too high, perhaps because of taxes or externalities, then everyone might agree that maximizing (1) is desirable. But for individual agents, aggregate inflation and output are givens; the best they can do is forecast inflation

accurately. The game consists then of the government choosing  $x$  and the public choosing  $x^e$ , with payoffs given by equations (1) and (2).

Now consider, as do Barro and Gordon, the Nash solution to the game in which both players move simultaneously. With both government and public maximizing given the other's decision, the solution is

$$x = b/a \quad \text{and} \quad x^e = b/a.$$

The model explains inflation as the Nash equilibrium to a policy game. The payoffs are  $u_g = -(1/2)b^2/a$  and  $u_p = 0$ , which is Pareto inferior to the zero-inflation solution ( $x = x^e = 0$ ) in which  $u_g = u_p = 0$ .

Barro and Gordon argue persuasively that the inefficiency stems from the government's inability to commit itself to a noninflationary policy. Suppose, for example, that the government were able to move first, committing itself to a particular rate of inflation. Then an intelligent government would choose  $x$  taking into account the public's response (namely,  $x^e = x$ ) and pick zero inflation.

But when the government cannot make prior commitments, it faces a problem in convincing the public that it will, in fact, choose zero inflation. For if the public believes this, the government has an incentive to inflate at rate  $x = b/a$ , thereby raising output and the government's payoff. Using the normalization  $a = b = 2$ , we can represent policy as a matrix game with two strategies ( $x, x^e = 0$  or 1), and payoffs

		public	
		$x^e = 0$	$x^e = 1$
government	$x = 0$	0, 0	-2, -1
	$x = 1$	1, -1	-1, 0.

(In each ordered pair the government's payoffs are listed first.) The problem from this point of view is that  $x = 1$  is a dominant strategy for the government: the payoffs are larger regardless of what the public does. The public, therefore, sensibly expects the government to inflate. The result is the Pareto-inferior solution  $x = x^e = 1$ .

Barro and Gordon then consider the possibility that the government can establish a reputation for avoiding inflation if the game is repeated infinitely many times. Let the government's payoff for the repeated game be

$$J_g = \sum_{t=0}^{\infty} c^t u_g(x_t, x_t^e), \quad 0 < c < 1,$$

with  $c$  a discount factor. Then Barro and Gordon (1983b), applying results similar to James Friedman (1971; 1977, ch. 8), show that the strategies

$$x_t^e = \begin{cases} x^* & \text{if } x_{t-1} = x^* \\ 1 & \text{otherwise} \end{cases}$$

$$x_t = x^*$$

do *not* constitute a Nash equilibrium when  $x^* = 0$ . The problem is that the government's benefit from cheating (the extra payoff of +1 when  $x = 1$  and  $x^e = 0$ ) is equal to its cost (the loss of 1 when  $x^e = 1$  and the government returns to zero inflation). But since the latter comes later, the discount factor ensures that cheating is a superior strategy and  $x^* = 0$  is therefore not a Nash equilibrium with the given "punishment" strategy. They go on to argue that some positive rates of inflation  $x^*$  can be sustained as Nash equilibria, and it seems clear that even zero could be sustained with a longer punishment interval if  $c$  is not too small.

A weakness of this analysis is that the punishment strategy played by the private sector (punish the government by playing  $x_t^e$  equal to 1 if  $x_{t-1}$  is not zero) is essentially arbitrary. Further, the equilibrium which is sustained depends critically on the form this punishment strategy takes. The infinite horizon game has multiple Nash equilibria, with no mechanism for choosing among them. The Kreps-Wilson (1982b) analysis of reputation, to which we now turn, avoids these problems and illuminates a number of other issues as well.

## II. Reputational Equilibrium

Consider now the possibility that the government may behave in one of two ways: it may behave as if it is rationally attempting to maximize the utility function (1) (a "wet" government); or it may behave as if it is committed irrevocably to pursuing a zero-inflation policy (a "hard-nosed" (H-N) government). Wet governments therefore have payoffs

		public	
		$x^e = 0$	$x^e = 1$
wet government	$x = 0$	0	-2
	$x = 1$	1	-1,

as in the previous section. Hard-nosed governments, however, behave as if their payoffs are

		public	
		$x^e = 0$	$x^e = 1$
H-N government	$x = 0$	0	0
	$x = 1$	-1	-1,

which we might derive by setting  $b = 0$  in the government payoff function (1). They therefore have no incentive to inflate, regardless of expectations. The public's payoffs are given by equation (2):

		public	
		$x^e = 0$	$x^e = 1$
government	$x = 0$	0	-1
	$x = 1$	-1	0.

The crux of the analysis is that the public does not know which type of government behavior it faces. As a result, even a wet government may choose not to inflate. By resisting inflation it develops a reputation for being hard nosed which it hopes will discourage expectations of inflation in the future. In this section we examine such a reputational equilibrium in a finitely repeated version of the Barro-Gordon policy game when the public is uncertain about the government's behavior. The analysis is identical to Kreps and Wilson (1982b, Sec. 3) in all essen-

tial respects. The solution concept is Kreps and Wilson's (1982a) sequential equilibrium, which enables us to find the solution recursively, starting with the final period.

The central feature of the model is the government's ability to manipulate its reputation. The government enters period  $t$ , say, with a reputation  $p_t$  equal to the public's probability that the government is hard nosed. By assumption both the government and the public know  $p_t$ . Both players then choose their best strategies, given the other's strategy and the impact of current behavior on the next period's reputation. The probability  $p_t$  is then revised in light of observed behavior according to Bayes' rule.

Each player's strategy is usefully characterized as a probability of playing zero in a mixed strategy: denoted  $z_t$  for the public and  $y_t$  for the government. Then the government's reputation next period,  $p_{t+1}$ , is zero if it inflates this period (or has ever inflated in the past) since  $H-N$  governments never inflate. Given no inflation, Bayes' rule gives the probability as

$$\begin{aligned} p_{t+1} &= \text{prob}(H-N|x_t=0), \\ &= \text{prob}(H-N \text{ and } x_t=0)/\text{prob}(x_t=0), \\ &= \text{prob}(x_t=0|H-N)\text{prob}(H-N) \\ &\quad / [\text{prob}(x_t=0|H-N)\text{prob}(H-N) \\ &\quad + \text{prob}(x_t=0|\text{wet})\text{prob}(\text{wet})], \end{aligned}$$

or

$$(3) \quad p_{t+1} = p_t / [p_t + (1-p_t)y_t].$$

In this game, as in the version of the chain store paradox analyzed by Kreps and Wilson (1982b, Sec. 2), the probability  $p_t$  is a sufficient statistic for past play and contains all the relevant information needed by the players to make optimal decisions.

Consider now the solution of the game. In the final period,  $T$ , a  $H-N$  government will always play  $x_T=0$ . The expected return for

a wet government is

$$\begin{aligned} (4) \quad J_g(T, p_T) &= z_T[y_T(0) + (1-y_T)(1)] \\ &\quad + (1-z_T)[y_T(-2) + (1-y_T)(-1)] \\ &= (2z_T-1)-y_T. \end{aligned}$$

Since this is declining in  $y_T$ , a wet government will always inflate in the last period:  $y_T=0$ . Similarly, the public's expected payoff is

$$\begin{aligned} J_p(T, p_T) &= z_T[p_T(0) + (1-p_T)(-1)] \\ &\quad + (1-z_T)[p_T(-1) + (1-p_T)(0)] \\ &= z_T(2p_T-1) - p_T. \end{aligned}$$

Thus if  $p_T > 1/2$  the public plays  $z_T=1$  ( $x_T^e=0$ ), if  $p_T < 1/2$  it plays  $z_T=0$ , and if  $p_T=1/2$  the public is completely indifferent about  $z_T$ . The equilibrium strategy in this case ( $z_T=1/2$  when  $p_T=1/2$ ) will be derived below from the equilibrium conditions for the preceding period. The value to the government to playing the game in the last period is therefore

$$v_g(T, p_T) = \begin{cases} 1 & \text{if } p_T > 1/2, \\ 0 & \text{if } p_T = 1/2, \\ -1 & \text{if } p_T < 1/2. \end{cases}$$

The value to the public is

$$v_p(T, p_T) = \max(-p_T, p_T-1).$$

In period  $T-1$ , the government must consider the impact of its behavior on its reputation in the final period. The expected two-period payoff is

$$\begin{aligned} J_g(T-1, p_{T-1}) &= z_{T-1}[y_{T-1}(0) + (1-y_{T-1})(1)] \\ &\quad + (1-z_{T-1})[y_{T-1}(-2) + (1-y_{T-1})(-1)] \\ &\quad + y_{T-1}v_g(T, p_T) + (1-y_{T-1})(-1). \end{aligned}$$

The last term reflects the fact that if the government inflates in period  $T-1$ , which it does with probability  $(1 - y_{T-1})$ , then its reputation is blown; the public will expect inflation in the final period and the government's payoff in that period is  $-1$ . The penultimate term is the probability of playing zero actual inflation in  $T-1$ , and then collecting the payoff in  $T$  associated with a reputation  $p_T$ , where  $p_T$  is given by equation (3). The expression reduces to

$$(5) \quad J_g(T-1, p_{T-1}) = 2z_{T-1} - 2 \\ + y_{T-1}v_g(T, p_T).$$

The public's two-period payoff is

$$J_p(T-1, p_{T-1}) = z_{T-1}(2q_{T-1} - 1) - q_{T-1} \\ + q_{T-1}v_p(T, p_T),$$

where  $q_{T-1} = p_{T-1} + (1 - p_{T-1})y_{T-1}$ .

The government now chooses  $y_{T-1}$  to maximize (5) subject to (3). For  $p_{T-1} > 1/2$ , this implies  $y_{T-1} = 1$ , hence  $p_T = p_{T-1} > 1/2$ ,  $v_g(T, p_T) = 1$ , and  $z_T = 1$ . That is, the government plays  $x_{T-1} = 0$  with certainty; its reputation does not change, but it is already sufficient to ensure that the public does not expect inflation in the last period. For  $0 < p_{T-1} < 1/2$ , the government plays zero inflation with probability

$$y_{T-1} = p_{T-1}/[1 - p_{T-1}].$$

If by chance it fails to inflate, its reputation for being hard nosed rises in the next period to  $1/2$ . Since  $p_{T-1} < 1/2$  it is clear that  $y_{T-1}$  is strictly less than one. But since  $y_{T-1}$  maximizes (5), this can only be true if  $v_g(T, p_T) = 0$ . From (4) we see then that  $z_T$  must be  $1/2$ , as we claimed earlier.

If  $p_{T-1}$  is exactly  $1/2$  then  $y_{T-1}$  is one and it appears that any value of  $z_T$  between one-half and one is consistent with equilibrium. We assume in this case that  $z_T = 1/2$ . This assumption is analogous to one made by Kreps and Wilson and has no material effect on the results.

The solution of the game as described has the property that both  $(x_T, y_T)$  and  $(x_{T-1}, y_{T-1}, x_T, y_T)$  are Nash equilibria. This recursive structure, which Kreps and Wilson (1982a) have labeled "sequential equilibrium," imposes a condition on the solution analogous to the principle of optimality. In period  $T-1$ , we only consider period  $T$  strategies which are themselves Nash equilibria. As a result, the equilibrium is dynamically consistent by construction.

With similar reasoning the solution can be extended to earlier periods. Equilibrium behavior is conveniently summarized as follows. (i) In period  $t$ , the private sector plays zero expected inflation with probability  $z_t$  given by

$$z_t = \begin{cases} 1 & \text{if } p_t > (1/2)^{T-t+1}, \\ 1/2 & \text{if } p_t = (1/2)^{T-t+1}, \\ 0 & \text{if } p_t < (1/2)^{T-t+1}. \end{cases}$$

(ii) A wet government plays actual inflation equal to zero with probability  $y_t$  given by

$$y_t = \begin{cases} 1 & \text{if } p_t > (1/2)^{T-t}, \\ \frac{p_t}{1-p_t} \frac{1 - (1/2)^{T-t}}{(1/2)^{T-t}} & \text{if } 0 < p_t \leq (1/2)^{T-t}, \\ 0 & \text{if } p_t = 0. \end{cases}$$

(iii) The probability of the government being hard nosed is revised in accordance with Bayes' rule:

$$p_{t+1} = \begin{cases} \frac{p_t}{p_t + (1-p_t)y_t} & \text{if } x_t = 0, \\ 0 & \text{if } x_t = 1 \\ & \text{or } p_t = 0. \end{cases}$$

(iv) The expected payoff to a wet government on entering stage  $t$  of the game with reputation  $p_t$  is given by

$$J_g(t, p_t) = 2z_t - (T - t + 1) \\ + y_t[v_g(t+1, p_{t+1}) + (T - t - 1)],$$

where  $v_g(t+1, p_{t+1})$  is the value of the game next period conditional on not inflating in period  $t$ . In equilibrium the value function for a wet government is therefore

$$v_g(t, p_t) = \begin{cases} t-T-1 & \text{if } 0 < p_t < (1/2)^{T-t+1}, \\ t-T & \text{if } p_t = (1/2)^{T-t+1}, \\ t-T+1 & \text{if } (1/2)^{T-t+1} < p_t \leq (1/2)^{T-t}, \\ t-T+2+i & \text{if } (1/2)^{T-t-i} < p_t \leq (1/2)^{T-t-i-1}, \end{cases}$$

for  $i = 0, 1, \dots, T-t-1$ ,  
and  $t = 1, 2, \dots, T-1$ .

### III. Reputation and Dynamically Consistent Policy: An Example

To get an idea as to what kinds of behavior are implied by the theory, let us look at an example. Suppose a wet government comes to power with a five-year term ( $T=5$ , with no possibility of reelection) and that at the beginning of its term it is strongly suspected of being wet. To be specific, let us say that it is believed to be hard nosed with probability lying somewhere between  $1/16$  and  $1/32$ , although none of the qualitative conclusions depend on these values.

The play progresses as follows. In period 1, the public chooses  $x_1^e = 0$  with certainty and the government chooses  $x_1 = 0$  with probability  $15p_1/(1-p_1) < 1$ . If  $x_1 = 0$  is actually played, the game continues with the government's reputation enhanced ( $p_2 = 1/2^4 = 1/16$ ). If the government inflates, its reputation is ruined, and the equilibrium is  $x = x^e = 1$  for the rest of the game.

In later periods, if the government has not yet inflated, its reputation rises just enough to induce the public to choose zero expected inflation with probability  $1/2$ . Three points are noteworthy. (i) Reputation is only enhanced ( $p_t > p_{t-1}$  given that  $x_{t-1} = 0$ ) if the government plays  $x_{t-1} = 0$  with probability less than one. Acquiring a reputation thus involves taking a risk. (ii) In each period after the first, given that actual inflation was zero in the preceding period, the public

randomizes with a constant probability of  $1/2$ . Thus there is a positive probability of getting  $x^e = 1$ ,  $x = 0$  and therefore a recession. The revised estimates that the government is hard nosed are not enough to discourage the public completely from playing  $x^e = 1$ . (iii) The probability that a wet government survives until the last period without ruining its reputation is just equal to  $p_1/(1-p_1)$ , so it pays to have a good reputation.

Let us consider now the problem of dynamic inconsistency and the definition of optimal policy. As Kydland and Prescott showed, the *ex ante* optimal policy is typically dynamically inconsistent, and therefore not credible. But the outcome of the best consistent policy is frequently worse than the *ex ante* optimal policy if the latter is credible.

Our own solution is, by construction, dynamically consistent and credibility is conveniently summarized by the reputation,  $p$ . It is easy to see that the sequential equilibrium is the best credible policy. In our example, the payoff to the government of following the consistent sequential equilibrium policy is  $v_g(1, p_1) = -3$ . Alternatively, suppose the government played  $x = 1$  in every period. The public, given  $1/16 < p_1 < 1/32$ , would play  $x_1^e = 0$  and  $x_t^e = 1$  ( $t = 2, \dots, 5$ ), giving the government a payoff of  $-4$ . The outcome involves actual inflation in every period, which is a surprise only in period 1. (If the private sector anticipated  $x_1 = 1$ , the government payoff would be  $-5$ .) Finally, if the government announced that it would never inflate, the outcome depends on whether it is believed or not. If  $p_1$  truly captures the public's beliefs, then the outcome is zero actual inflation in each period, but zero expected inflation with certainty in period 1 and with probability  $1/2$  thereafter, giving the government an expected payoff of  $-4$ . If the announced zero-inflation policy were believed (because of an associated constitutional amendment, for example), then the government's payoff would be zero.

It is clear, then, that the sequential equilibrium is dominated only by the fully believed zero-inflation commitment, given the behavior of the public and their beliefs about

the government. It is always at least as good as pursuing a zero-inflation policy "come what may," in the face of a poor reputation. Thus, in the presence of public skepticism ( $p_1 < 1$ ), and in the absence of irrevocable commitments, the sequential equilibrium is at least as good as (and usually better than) the time-inconsistent *ex ante* optimal policy of setting  $x_t = 0$  in all periods. The concept of sequential equilibrium removes the ambiguity from the definition of optimal policy.

The analysis also sheds light on the results of Barro and Gordon. If a government is optimizing over a long time horizon ( $T$ ), and its initial reputation is "good" in the sense that  $p_1$  is much larger than  $(1/2)^T$ , then the solution will have the following property. There will be an initial period in which zero inflation is expected, and zero actual inflation occurs. The first period in which there is a departure from this pattern is period  $n$ , where  $n$  is the smallest integer for which  $(1/2)^{T-n} > p_1 > (1/2)^{T-n+1}$ . In this period the government will begin to create inflation with some nonzero probability. In subsequent periods, conditional on having observed zero inflation, the private sector will expect zero inflation with probability  $1/2$ .

As  $T$  increases for given  $p_1$ ,  $n$  increases also. In contrast to Barro and Gordon, in a game with a sufficiently long time horizon this analysis leads to the conclusion that for any nonzero initial reputation ( $p_1 > 0$ ) there will be an initial period (which tends to infinity as the horizon tends to infinity) in which zero inflation is the equilibrium outcome. This is supported by the "punishment strategy" for the private sector which makes  $x_t^e = 1$  for all  $t > s$  if  $x_s = 1$ . This strategy is rational if the government's behavior is used to draw inferences about its preferences. By contrast, Barro and Gordon (1983b) assume that the public "punishes" a deviant government for one period, without rationalizing this assumption, and argue that zero inflation cannot be supported in an infinite-horizon game except by the use of rules to lend credibility to policy announcements. Our analysis would change somewhat if we introduced a discount factor. As in Barro and Gordon, a small discount factor makes it harder to sustain low inflation.

#### IV. Final Remarks

The Kreps-Wilson analysis fits many of the observed features of macroeconomic policy quite well. First, it is commonplace to hear politicians reassure us that they are serious about beating inflation. These statements are correctly regarded with skepticism, since both hard-nosed and wet governments have an incentive to establish reputations for being tough—that is, raise  $p$ . Conversely, governments frequently complain that their actions are thwarted by the "mistaken" expectations of labor unions, big business, and the gnomes of Zurich. Note, for example, that even a hard-nosed government will suffer persistent output losses half the time as the public randomizes, if its initial reputation is bad ( $p$  is small). Wet governments will also induce recessions until, by chance, they reveal themselves to be wet. From then on the inflationary equilibrium ( $x = x^e = 1$ ) results.

Second, the model provides an account of the political business cycle without relying on voter myopia. At the same time it explains the inflationary bias of policy without recourse to nonlinearities in the Phillips curve. In the Nordhaus model, governments deflate early in their terms and inflate later since voters place more weight on events immediately preceding the next election. The strategy successfully raises output because the public is doubly myopic: they forget the low output early in the term and they fail to predict the inflation later. In the Kreps-Wilson framework, inflation at the end of the term is the rational response of a government that cares about employment. It works, on average, because the public is uncertain about the government's true character. Voters are not myopic; they simply do not have all the information.

The logic is just the opposite of conventional theory of the political business cycle. Instead of having a government create a pre-election boom in order to increase its chance of reelection, our analysis generates a pre-election boom as the solution to a game with a wet lame-duck government. In fact, if there were a chance of reelection, the incentive to preserve reputation may actually restrain the spending spree.

Third, the analysis suggests that governments may try to appoint central bankers with reputations for fighting inflation, even if their own preferences place positive weight on employment. By doing so they minimize the costs associated with uncertainty about policy ( $v_p$  is highest when  $p$  is zero or one) and with the credibility problem wet governments have with noninflationary policies. Autonomous central banks thus act as a precommitment device which may help to make noninflationary policies more credible and less costly.

Despite these apparent strengths of the analysis, a few caveats are in order. On the technical side, the assumptions that there are only two choices for inflation may be undesirably restrictive. The lack of dynamics relating inflation and output to their past values is also troublesome. The possibility of an intransigent public sector is discussed in our earlier paper (1984).

We also have some doubt that the model explains why we have had relatively high inflation during the past fifteen years, but not before. James Tobin, for one, disagrees that inflation was a policy choice derived from a desire to raise employment.

Today a widespread version of recent history is that governments deliberately sought higher inflation in order to reduce unemployment....As an explanation of recent inflation in the United States this account is enormously exaggerated....The 1966-69 ride up the Phillips curve was not a conscious choice of novel macroeconomic strategy but a timeworn political decision about wartime finance. Against the advice of his Keynesian advisors, President Johnson chose for his own reasons of domestic and international politics not to ask Congress for increased taxes to finance his ill-starred escalation of the conflict in Indochina.

[1981, pp. 21-22]

But whatever the origin of the inflation, we think the model helps to explain why disinflation took so long and was so painful. By the mid-1970's, the public was highly skeptical of each new attempt to fight inflation,

since so many attempts had been abandoned in the past. Presumably even tough-minded policymakers faced a doubtful public. As a result, governments who cared about employment were often forced (probabilistically) to continue inflationary policies. Governments who wished only to stop inflation could not easily persuade the public of this fact, and therefore induced severe protracted recessions when they tried.

# The Competitive Effects of Vertical Agreements?

By WILLIAM S. COMANOR AND H. E. FRECH III\*

For many years, there were few distinctions drawn between horizontal and vertical agreements. Both were considered anticompetitive and subject to *per se* condemnation under the antitrust laws. Recently, however, this approach has come under attack, and what was once the conventional wisdom is no longer so. Indeed, there is growing acceptance of the view that vertical agreements can rarely have anticompetitive consequences. *Per se* legality would then be the appropriate standard.

In this paper, we investigate the competitive implications of a particular vertical agreement: the imposition of exclusive dealing requirements by a manufacturer on his distributors. However, to maintain the focus of the analysis, we do not consider ultimate welfare gains or losses.

In an early application of economic analysis to this practice, Aaron Director and Edward Levi (1956) suggest that exclusive dealing would be anticompetitive if it raised entry costs for rivals. Our object, following this conjecture (see their p. 293), is to examine the market conditions under which exclusive dealing impedes entry.

Howard Marvel (1982) dealt with the practice of exclusive dealing. He provides an efficiency rationale for exclusive dealing, ignores the prospect that anticompetitive effects may follow, and concludes that "exclusive dealing ought therefore to be treated as legal, *per se*" (p. 25). This paper examines the possible anticompetitive effects neglected by Marvel.

## I. Market Conditions for Exclusive Dealing

At this point, we construct a simple model of exclusive dealing arrangements. Our object is not a search for generality, but rather to illustrate both the conditions and the manner by which exclusive dealing may have anticompetitive effects.

Our first assumption is that there exists a single dominant manufacturer producing a single product at constant unit costs  $c$  in the relevant range of output. There are two classes of consumers for the firm's product. Members of the first group, indicated as Class A, believe it superior to any rival brand. These consumers are identical and purchase the dominant firm's product rather than a competing brand so long as its price to them is no higher than  $\alpha$  above the rival's price. Their individual demand curves for this product therefore lie above the corresponding demand curves for all other products by the same amount  $\alpha$ , which reflects the per unit value of Class A consumers' brand preferences.

The remaining consumers, members of Class B, view the products of all sellers as identical. For convenience, we assume that the individual demand curve of Class B consumers is identical to that of Class A consumers for all brands except that of the dominant manufacturer. The aggregate demand curve therefore depends on the number of consumers in each class as well as the size of  $\alpha$ .

Consumers obtain the product through independent distributors. Since resale between customers is possible, discrimination between the two classes of consumers is not feasible, and the same price is charged to all.

We assume further that imperfect competition exists among established distributors. Scale economies in distribution create segmented local markets. As a result, established distributors do not compete on a large,

\*Professors of Economics, University of California, Santa Barbara, CA 93106. We thank the Committee on Research of the Academic Senate, University of California-Santa Barbara, for financial support. Valuable comments were received from seminars at the universities of Chicago, Northwestern, Toronto, and Illinois, the Federal Trade Commission, and at our own university.

dense plain. They have some degree of market power and set distribution margins above their marginal costs.

Distribution margins in these circumstances are determined by spatial competition of the type modelled by Steven Salop and others.<sup>1</sup> For our analysis, a change in either the manufacturer's price or his policy regarding exclusive or nonexclusive dealing would affect both demand and costs for the distribution function. However, it would be extremely complex and lead us away from our main subject to incorporate formally these effects. We therefore adopt the simplifying assumption that the number of distributors and the imperfectly competitive distribution margin is constant with respect both to the manufacturer's price and policy regarding exclusive dealing. This margin is indicated by  $\gamma$ .

This simplifying assumption actually comports with reality better than one might expect. Due to the presence of economies of scope, distributors handle many, perhaps thousands, of products. Therefore, the actual number of distributors is unlikely to be much affected by what happens with any single product. And as a result, equilibrium margins which depend strongly on the number and location of rivals would be relatively stable.

Distribution is a multiproduct activity that is subject to economies of scope.<sup>2</sup> These economies imply that

$$(1) \quad C(q_1, \dots, q_n) < C(q_1) + C(q_2) + \dots + C(q_n),$$

where  $C(q_1, \dots, q_n)$  indicates the total costs of distributing a vector of  $q_i$  goods. The terms on the right-hand side of expression (1) indicate the total costs of distributing the same vector of goods separately.  $C(q_1)/q_1$  is therefore the unit cost of distributing the first good without realizing economies of scope. It represents the minimum distribution margin

that can be charged by single-product distributors, and is indicated by  $\delta$ . In the presence of economies of scope,  $\delta$  exceeds  $\gamma$ .

## II. Distribution without Exclusive Dealing

First, consider the case where the manufacturer ignores the prospect of entry. Since established distributors set a distribution margin of  $\gamma$ , the market demand curve facing the manufacturer is the consumer demand curve shifted downward by that amount. The dominant manufacturer maximizes profits, given that demand curve.

Now consider the case where a dominant manufacturer takes the prospect of entry into account. To focus the discussion, let the entrant have the same constant manufacturing costs as the established firm. Although Class B consumers view his product as identical to that of the original manufacturer, Class A consumers consider his product less valuable so their aggregate demand price is lower by  $\alpha$  per unit.

While there are surely strategic interactions between entrant and established firm, we abstract from these issues and assume that the entrant behaves competitively regardless of the actions of the dominant firm.<sup>3</sup> He enters if he can obtain a price of  $c$  for his product and sets this price in all circumstances. Not only does this assumption simplify the analysis of oligopolistic interdependence between entrant and established firm, it represents that strategic choice on the part of the entrant that is most conducive to competition.

Even in these circumstances, there are two possible strategies which can be adopted by the original manufacturer. The first, a low-price strategy, is to set his price at  $c$ . Entry is prevented and the entire market retained by the original manufacturer. This strategy, however, leads to zero profits. Since a better one exists, a low-price strategy is not adopted.

Following a high-price strategy, the firm sets a higher limit-entry price that retains sales to Class A consumers but sacrifices

<sup>2</sup>For a discussion of economies of scope, see Robert Willig (1979, pp. 346-47).

<sup>3</sup>See F. M. Scherer (1980, pp. 229-66).

sales of Class B consumers to the entrant. The manufacturer's price is now  $(c + \alpha)$ , which leads to a final price to consumers of  $(c + \alpha + \gamma)$ . The entrant's price is merely  $c$  and the resale price of his product is  $(c + \gamma)$ . These prices are summarized below:

(2)	$P_M = c + \alpha$	Manufacturer's price
	$P'_M = c + \alpha + \gamma$	Distributor's price of original manufacturer's product
	$P_E = c$	Entrant's price
	$P'_E = c + \gamma$	Distributor's price of the entrant's product.

Within the confines of this model, sales to Class A consumers are of the original manufacturer's product while sales to Class B consumers are of the entrant's product. The original manufacturer's profits result from his product differentiation advantages, represented by  $\alpha$ , while the distributor's profits, if any, rest on his locational or other advantages, indicated by  $\gamma$  less distribution costs.

### III. Distribution with Exclusive Dealing

Even with exclusive dealing, contracts remain simple. Complex contracts that effectively integrate the manufacturer and distributor are assumed too costly to reach.

After the dominant manufacturer has imposed exclusive dealing requirements, the new entrant must distribute his product through an alternate channel and bear higher distribution costs. The relevant prices for the entrant's product are now

(3)	$P_E = c$	Entrant's price
	$P'_E = c + \delta$	Resale price of the entrant's product.

The original manufacturer can benefit from the differential costs of distribution. This factor is the key to understanding the possible anticompetitive effects of exclusive dealing.

Again, two strategies are possible. Following a low-price strategy, the manufacturer sells to both classes of customers. In this case, his final price must be no higher than the corresponding price of the entrant's product, and is thereby given by

$$(4) \quad P'_M = P'_E = c + \delta.$$

From this price must be deducted the standard distribution margin, so that the manufacturer's price to his distributors is

$$(5) \quad P_M = c + \delta - \gamma.$$

Compare the price to consumers in the presence of exclusive dealing with that charged in its absence. The relevant comparison is with prices set under a high-price strategy, as reported in expression (2). Clearly, Class B customers are worse off in the presence of exclusive dealing, since they would be content to purchase the entrant's product. Class A customers, on the other hand, purchase the original manufacturer's product in either case and could be better off or worse off. They face higher prices with exclusive dealing so long as

$$(6) \quad \delta > \alpha + \gamma,$$

which can be rewritten,

$$(7) \quad \alpha < (\delta - \gamma),$$

and lower prices where these inequalities are reversed.

An economic interpretation of this result is that prices are higher to Class A consumers under exclusive dealing so long as the increased costs of distributing the product alone exceed the brand preference shown for the dominant firm's product. Where this inequality is reversed, however, Class A customers face lower prices in the presence of exclusive dealing.

With a high-price strategy, the manufacturer sets the highest price possible for Class A customers, and accepts the loss of Class B customers. The final price now is the entrant's price plus  $\alpha$ . Since the entrant's resale price is  $(c + \delta)$ , the original manufacturer's price

to consumers is readily determined, and also his price to established distributors:

$$(8) \quad \begin{aligned} P'_M &= c + \alpha + \delta, \\ P_M &= c + \alpha + \delta - \gamma. \end{aligned}$$

At these prices, Class A customers purchase the original manufacturer's product despite a price differential of  $\alpha$ . Class B customers, however, purchase the entrant's product through alternate channels of distribution. In this case, we find that prices to both classes of customers are higher in the presence of exclusive dealing.

The implications of this analysis are striking. Under the specified market conditions, the original manufacturer profits by imposing exclusive dealing requirements on his distributors, regardless of his choice of pricing strategy.

#### IV. Exclusive Dealing with Distributor Choice

In this section, we ask whether the actions of distributors can constrain manufacturer behavior. First, consider the case where brand preferences by Class A consumers are relatively strong, so that

$$(9) \quad \alpha > \delta - \gamma.$$

In this situation a distributor knows that if he did not abide by the exclusive dealing requirements, his sales would be limited to Class B customers. Class A customers would continue to purchase the original manufacturer's product even at a price which encompassed higher distribution costs. Therefore, to go along with this requirement, the distributor must be certain that his profits under exclusive dealing are at least as great as would be earned on sales of the entrant's product to Class B customers alone. The profit comparison is different for the two pricing strategies so we consider them separately.

With a low-price strategy, the original manufacturer retains sales to both classes of customers. Since unit costs and margins are assumed constant, distributor profits depend

on which choice provides the greater volume. The condition for distributor acceptance of exclusive dealing is that

$$(10) \quad Q_B^E(c + \gamma) \leq Q_A^M(c + \delta + \lambda) + Q_B^M(c + \delta + \lambda),$$

where the subscripts refer to sales made to a particular class of customers and the superscripts refer to the manufacturer of the product sold:  $M$  for the original manufacturer and  $E$  for the entrant. The terms in parentheses refer to the prices associated with the indicated quantities.

In this expression, we introduce  $\lambda$  which measures the original manufacturer's markup over costs. The manufacturer selects the highest possible value of  $\lambda$  consistent with distributor choice, which is that value which makes expression (10) an equality. Where the value of  $\lambda$  is positive, the distributor accepts exclusive dealing arrangements imposed by the original manufacturer even at a price higher than the latter's preferred limit-entry price. If so, the constraint imposed by distributor choice is not binding and the limit-entry prices are those stated above. On the other hand, where  $\lambda$  is negative, the distributor choice constraint is binding and the relevant prices are lower by this amount.

The former result seems particularly likely in this case. So long as the number of Class A customers is sufficiently large, the first term on the right-hand side of expression (10) will lead the inequality to hold despite any depressing effect on quantity of higher manufacturer prices.

When the original manufacturer pursues a high-price strategy, a different comparison is relevant. In this case, the distributor is limited to Class A customers if he accepts exclusive dealing and Class B customers otherwise. The condition for distributor acceptance of exclusive dealing is now

$$(11) \quad Q_B^E(c + \gamma) \leq Q_A^M(c + \delta + \alpha + \lambda).$$

Unlike the previous comparison, this inequality is unlikely to be satisfied for positive  $\lambda$ . It depends critically on the relative sizes of

the two classes of customers. Larger numbers of Class B customers will generally lead the distributor to reject exclusive dealing requirements, and as a result, they would not be imposed.

Consider the special case where there are equal numbers of the two classes of customers. The aggregate demand schedules of each class are here identical except that the demand for the original manufacturer's product by Class A customers lies above that of Class B customers by the amount  $\alpha$ . In this case, the inequality in expression (11) does not hold unless  $\lambda$  is sufficiently negative so that the right-hand side quantity is larger. The constraint imposed by distributor choice is now binding, and the original manufacturer's price is lower than previously determined.

While it is therefore possible for the original manufacturer to secure exclusive dealing arrangements by setting a sufficiently low price, it is not likely to be in his interests to do so. The ability of the original manufacturer to pursue a high-price strategy along with exclusive dealing arrangements is limited by distributor choice.

Under weak brand preferences, the inequality given in expression (9) is reversed, and the original manufacturer's position is weaker than before. Again, the distributor's profits depend on his quantity sold. Where the original manufacturer follows a low-price strategy, the distributor's condition for accepting exclusive dealing requirements is given by

$$(12) \quad Q_A^E(c + \gamma) + Q_B^E(c + \gamma) \\ \leq Q_A^M(c + \delta + \lambda) + Q_B^M(c + \delta + \lambda).$$

Recall that the demand of Class A consumers for the original manufacturer's product is identical to their demand for the entrant's product at a price lower by  $\alpha$ . Therefore, we can compare this demand for the two products by adjusting the prices indicated for the original manufacturer's product. Focus here on the first term on each side of expression (12). Letting  $\lambda$  temporarily be zero, the left-hand side price for Class A

consumers is  $(c + \gamma)$  while the adjusted right-hand side price is  $(c + \delta - \alpha)$ . The latter is greater than the former if

$$(13) \quad \delta - \alpha > \gamma,$$

which implies

$$(14) \quad \alpha < \delta - \gamma.$$

This is precisely the case we are considering. The effective price for Class A customers is therefore higher, the quantity smaller, and the inequality is not supported by these consumers. The same result applies for Class B customers, where the higher price on the right-hand side leads to smaller quantities, which again is contrary to the indicated inequality and thereby to the acceptance of exclusive dealing.

To this point, our comparisons assume that prices are unchanged from limit-entry values so that  $\lambda$  is zero. Exclusive dealing, however, will be accepted at some negative value of  $\lambda$ . In this case, distributor choice imposes a binding constraint on manufacturer decisions, and prices must be lowered from limit-entry values to achieve exclusive dealing.

The corresponding comparison for a high-price strategy in the presence of weak brand preferences is given by

$$(15) \quad Q_A^E(c + \gamma) + Q_B^E(c + \gamma) \\ \leq Q_A^M(c + \delta + \alpha + \lambda).$$

So long as there are a substantial number of Class B consumers, this inequality is unlikely to be satisfied, and exclusive dealing will not be practiced. Again, distributor choice imposes a binding constraint on the decisions of the original manufacturer.

We conclude that exclusive dealing is more likely where brand preferences are strong. Furthermore, distributors are much less likely to abide by exclusive dealing where high-price strategies are followed. Low-price strategies which attract both classes of consumers to established distributors and to the original manufacturer are a far more likely outcome.

### V. Exclusive Dealing for Entry Deterrence

In this section, we consider the conditions under which actual prices may exceed the limit-entry prices reported above. What is relevant here is the ability of the original manufacturer to make a credible threat or commitment to respond strategically to a new rival and thereby charge higher prices.

With exclusive dealing requirements, the original manufacturer can exclude rivals with limit-entry prices that exceed costs, which is not otherwise possible. Moreover, if the original manufacturer can commit himself to this price if entry occurs and can communicate this commitment to prospective entrants, he can charge more than the limit-entry price.<sup>4</sup> While this type of action is of course independent of exclusive dealing, that policy increases its feasibility.

With exclusive dealing, the original manufacturer's limit-entry price provides positive profits while it offers no profits otherwise. The threat to contest vigorously the entry of a new manufacturer is now more plausible. Exclusive dealing thereby increases the credibility of the threat to exclude rivals and contributes to entry deterrence.

The price that the original manufacturer actually sets depends on the feasibility of lowering his price at the onset of entry. Where a successful commitment can be made, he is *not* limited to the limit-entry prices reported above. For this reason, *it is the presence of exclusive dealing rather than the specific limit-entry prices reported above which is critical for entry deterrence.*

### VI. An Application

In 1977, C. R. Laurence Co. filed suit in Los Angeles against the General Electric Company alleging, among other things, that the latter had attempted to impose exclusive dealing requirements and had cut off all sales

when these requirements were not followed.<sup>5</sup> That case provides a useful example of the circumstances in which exclusive dealing arrangements may be imposed by manufacturers as well as the anticompetitive consequences which may follow.

The suit concerned silicone sealants, a new and greatly advanced product used in the glazing industry. The leading U.S. manufacturer of silicone sealants was the General Electric Company, whose national market share reached about 75 percent during the mid-1970's. The product had been developed and patented by the French chemical company, Rhone-Poulenc, and G.E. was an early licensee.

Silicone sealants are sold through distributors who sell many other products as well. C. R. Laurence was a large distributor, and accounted for between 7 and 9 percent of total G.E. sales of sealant during this period. Although silicone sealants represented only about 2 to 3 percent of total C. R. Laurence sales, they were highly visible since most customers require some form of sealant. Many customers therefore pay particular attention to its price.<sup>6</sup>

As an early product on the U.S. market, the G.E. brand acquired a strong following, and many purchasers were willing to pay a substantial premium. Others, however, sought the brand with the lowest price.

There appear to be substantial economies in distributing sealant in the same process and location as other glazing supplies. Laurence provides an inventory of 15,000 different products which buyers purchase and use in conjunction with sealant. Distribution of sealants through other outlets would therefore be inefficient.

<sup>4</sup>For discussion of the importance of threats and commitments for oligopoly behavior, see Lester Telser, (1966) and Salop (1979b).

<sup>5</sup>*C. R. Laurence Co. v. General Electric Co.* (1977). All of the information presented in this section was obtained from the complaint in this matter or from interviews with Donald E. Friese, Vice-President and General Manager, C. R. Laurence Co. on October 6 and 20, 1982. Both the complaint and a record of these interviews is available from the authors on request. No data obtained from General Electric or its competitors during the course of discovery in this matter were used in the preparation of this paper.

<sup>6</sup>Donald Friese (1982).

In addition to economies of scope, there appear to be scale economies as well. C. R. Laurence had gained a leading position throughout California with a market share of between 30 and 35 percent. No other distributor was even one-third as large. With this scale of operation, Laurence provided various delivery and credit services to "good" customers. Moreover, its distribution margin was sufficient to generate a substantial return and make it a highly profitable operation.

In the mid-1970's, Rhodia sought to enter the U.S. market for silicone sealants with a highly comparable product that C. R. Laurence believes to be "almost exactly the same" (see Friese). Rhodia is the American subsidiary of the same French chemical company, Rhone-Poulenc, which had developed this product and manufactured it in Europe for many years. Moreover, its price to distributors was much lower than G.E.'s price.

General Electric learned that C. R. Laurence was distributing Rhodia products in late 1975. Even though the latter had been a leading distributor of silicone sealants, G.E. terminated Laurence's distributorship on June 1, 1976. Throughout the industry, it was believed that C. R. Laurence was dropped as an authorized distributor of G.E. products precisely because it started to carry Rhodia products. Apparently, G.E. was willing to eliminate even one of its leading distributors if a rival product was handled. Subsequently, at least through the period of the litigation, no other major distributor of G.E. products also sold the Rhodia brand.

The antitrust action which followed emphasized the anticompetitive effects of imposing exclusive dealing arrangements in this industry. Without the availability of distributors like C. R. Laurence in many market areas, Rhodia found it more difficult and costly to sell in the United States. Exclusive dealing arrangements were apparently used to raise the costs of entry at the manufacturing stage of production, and to maintain G.E.'s dominant market position.

## VII. Conclusions

The current state of opinion towards vertical arrangements such as exclusive dealing

has shifted dramatically from one extreme to the other. Rather than being considered as anticompetitive, they are now frequently viewed as procompetitive.

In this regard, we recall Thomas Kuhn's statement that "there are losses as well as gains in scientific revolutions, and scientists tend to be peculiarly blind to the former" (1970, p. 167). The emergence of a new position as to the competitive implications of vertical arrangements represents a scientific revolution in the economics of market relationships, and we need to be careful not to go too far. In regard to exclusive dealing, we are in danger of doing just that.

The policy conclusions which follow from our analysis are evident. Unless one posits prohibitive costs of judicial determination, exclusive dealing arrangements should not be viewed as per se illegal, but neither should they be viewed as per se legal. A full analysis of the market conditions under which they are practiced is required to determine whether there are anticompetitive effects. Moreover, this analysis does not appear unusually complex or difficult by antitrust standards. Our identification of a plausible set of circumstances where exclusive dealing arrangements have anticompetitive implications suggests an antitrust standard of the "rule of reason."

# Enlistments in the All-Volunteer Force: Note

By CHARLES DALE AND CURTIS GILROY\*

In their 1983 article on the determinants and forecasts of military personnel supply, Colin Ash, Bernard Udis, and Robert McNown (A-U-M) provide evidence of "...lower pay elasticities than had been previously estimated, [and] no significant effect of unemployment on recruitment..." (p. 147). These findings are derived from a model which first appeared in McNown et al. (1980). While the forecasting accuracy of their analysis is encouraging, we have also been able to predict future military accessions with a very different set of estimating equations, a variant of those found in our earlier article (1983). These equations are quite robust in yielding both sizable and significant pay and unemployment elasticities.

In Section I, we specify a time-series model from which are derived relatively large pay and unemployment effects, and we compare these results to those obtained by A-U-M. In Section II, this model is used to predict future Army enlistments of nonprior service male high school graduates.

## I. An Alternative Time-Series Model

Ash et al. failed to find an unemployment effect on enlistments because they did not have available the most appropriate data for estimating their equations. They used data on accessions and estimated their model over the draft and postdraft eras (20 semiannual observations from 1967: II through 1976: II). We benefited from special monthly data

tabulations on enlistment contracts signed provided to us by the Defense Manpower Data Center, and estimated our model over the all-volunteer force period (78 monthly observations from 1975 (10) through 1982 (3)).

Although A-U-M properly acknowledged that their theoretical model is formulated on applications to enlist, or "contracts," their empirical analysis is based on accessions (p. 146). We will show here that our use of contracts data produces results that are more in agreement with both economic theory and a priori expectations.

We agree with A-U-M that contracts, rather than accessions, are the correct data to use. Contracts are supply determined—individuals may sign contracts to enlist now, but actually begin their enlistment periods up to a year later. Accessions, on the other hand, are more demand determined by recruiters, since recruiters normally have three-month quotas to fill. Thus, contracts data are the appropriate type to use for estimating military supply equations. Although we have estimated equations for each of the four branches of the armed services as well as for white and nonwhite racial groups, we limit our analysis here to the Army model.

We have not attempted to replicate the A-U-M study exactly, for several reasons. First, they used *all* male Army accessions as the dependent variable, while we estimate only enlistment contracts of *high school graduates*, the group which is of most interest to the Army. Second, they used semiannual observations, which helped to smooth out some of the seasonal fluctuations in the data, but we are better able to account for seasonality with a quarterly dummy variable. Finally, we have included important educational variables in our equations; attempting to add them to A-U-M's equations leads to severe multicollinearity problems. Since our central point is that enlistment contracts, rather than accessions, are the proper data to

Notes: *t*-ratios are shown in parentheses. Dependent Variable is  $A/P$  where  $A$  = Army accessions or contracts of male nonprior service high school graduates and  $P$  = male population of 16-19-year-olds. Independent Variables are  $UM$  = unemployment rate of all males 16-19-years-old,  $W-1$  = ratio of first-year military compensation (including basic pay, allowances for quarters and subsistence, and the federal tax advantage) to average weekly earnings in the private economy, with a 1-month lag,  $W+4$  = wage ratio with a 4-month lead,  $GI$  = dummy variable = 1 in December 1976, when the GI bill expired, and = 0 everywhere else,  $BILL$  = Maximum monthly benefit for a GI bill beneficiary without dependents, deflated by the Consumer Price Index. Variable is set = 0 after December 1976,  $VEAP$  = maximum monthly benefit for a VEAP beneficiary without dependents, deflated by the consumer price index. Variable is set = 0 before January 1977,  $KICK$  = maximum value of "kicker" payments—amounts over and above VEAP benefits to those enlisting in designated military specialties—deflated by the Consumer Price Index,  $TARGET$  = binary variable = 1 from November 1979 to August 1981 (a period characterized by special recruiting policies targeted to the high school graduate population), and = 0 everywhere else,  $Q3$  = seasonal dummy = 1 in July, August and September, and = 0 everywhere else.

<sup>a</sup>Significant at .05 level.

<sup>b</sup>Significant at .01 level.

use in studies of this type, the exact form of the equations used is not crucial to our argument.

The distinction between contracts and accessions data is extremely important and may be seen in Figures 1 and 2. In Figure 1, the seasonally unadjusted 16 to 19-year-old

male unemployment rate is superimposed on male Army contract data. The correlation is certainly not perfect, but there is, nonetheless, a visible relation between unemployment and contracts signed. In contrast, the accessions data in Figure 2 clearly show how the expected seasonal pattern predominates,

as most high school graduates access in the summer, regardless of when they sign their contracts.

An equally dramatic difference between our contracts data and the A-U-M accessions data may be seen by considering the December 1976 expiration of the GI bill. The GI bill was a noncontributory educational program which was replaced in January 1977 by the less generous Veterans' Educational Assistance Program (VEAP). There was, consequently, a tremendous rush to sign contracts in December, 1976—a classic economic supply response—as shown in Figure 1. The actual accessions, however, were very low in December 1976, as Figure 2 shows, since relatively few people begin their enlistment tours in December. Again, contracts data rather than accessions data are shown to be the more appropriate series for testing this supply model.

In order to make meaningful comparisons of results from using identical equations with accessions data and contracts data, the 1975–82 time period was chosen—years during which both the all-volunteer force (*AVF*) was in existence and the requisite data were available. Limiting the analysis to the *AVF* period avoided the problem of mixing up the draft and postdraft years which required A-U-M to incorporate a "draft threat" variable in their estimating equation. Using only *AVF* years permits a purer test of the supply response.

The variables included in the equation were the male teenage unemployment rate (*UM*); the ratio of military pay to civilian earnings (*W*); three variables to measure educational benefits (*GI*, *BILL*, and *KICKER*); recruiter effort (*TARGET*); and a seasonal dummy (*Q3*). These variables are described in Table 1.

Roughly approximating A-U-M, we estimated equations with a lagged relative pay rate term (Table 1, cols. a and b), but did not obtain reasonable results with either accessions or contracts data. The equation using accessions data produced many "wrong" signs, and the contracts data equation produced statistically insignificant results for most variables.

TABLE 2—PAY AND UNEMPLOYMENT ELASTICITIES FOR ARMY ENLISTMENT RATES

Study	Elasticities	
	Pay	Unemployment
Accessions Data:		
McNown et al. (p. 121)	.816	.045

D and G (Table 1, col. d) <sup>b</sup>	3.9	.81

<sup>a</sup> Our earlier paper.

<sup>b</sup> This paper.

The preferred model is the one that appears in columns c and d in Table 1. The distinguishing feature of these equations is the four-month lead on the pay variable—not attempted until the present work, but which was suggested by Harry Gilman (1970). A four-month lead produced a better statistical fit than three or five month leads.

Columns c and d of Table 1 clearly show the effect of using contracts data vs. accessions data. The economic supply response is shown by the unemployment term which is large and statistically significant in the contracts equation, a result one would expect from both Figure 1 and with what recruits themselves are reporting; it is insignificant in the accessions equation. Indeed, in a recent survey of enlistees into the Army, over 40 percent mentioned unemployment as a factor (Timothy Elig et al., 1982). The supply response expected by the expiration of the GI bill in December 1976 is strongly picked up by the variable *GI* in the preferred contracts equation, but that variable even has the wrong sign in the accessions equation. All other education variables in the contracts equation are also statistically significant and display the correct signs. Finally, the variable *W* + 4 shows that relative pay is also an important factor—in both size and significance—in the enlistment decision.

Table 2 summarizes the differences in pay and unemployment elasticities from equations estimated with accessions and contracts data. Both the unemployment and pay terms show up much more clearly in the contracts equations.

TABLE 3—FORECASTS OF ARMY ENLISTMENTS OF MALE NONPRIOR SERVICE HIGH SCHOOL GRADUATES  
(Thousands of Contracts)

	FY81	FY82	FY83	FY84	FY85	FY86	FY87
D and G (1983)	78.1	97.1	95.9	82.6	72.7	66.5	61.9
D and G (Present Work)	75.8	94.0	87.5	75.7	66.8	59.5	52.4
Actual	79.9	95.6					

Note: FY82 actual is through June 1982 at an annual rate; FY87 projections are 3-month projections at annual rates.

## II. Forecasts of Army Enlistments

Ash et al. correctly point out that forecasting accuracy is an important criterion for the usefulness of an econometric model, so we report our projections of Army enlistments in Table 3. We assumed military pay will be frozen in fiscal year 1984, and military and civilian pay will increase at 6 percent per year from fiscal year 1985 onward. Our earlier work shows more optimistic projections because we did not anticipate any pay freezes. The overall trend in Army enlistments is clearly downward, largely due to a decreasing youth population and projections of declining unemployment rates.

Predicted Army enlistments from both our earlier paper and the present work are close to the actual values, differing by between 2–5 percent in fiscal year 1981 and about 2 percent in fiscal year 1982. It is not possible, however, to compare our forecasts with those of A-U-M since they did not provide projections beyond 1979.

We conclude by noting that we agree with A-U-M's conclusion that "current military pay policy might be inadequate to meet manpower requirements in the 1980's" (p. 154). Our results strongly support the view that it is important to maintain the comparability of military pay relative to civilian pay,

especially in the face of both unfavorable demographic trends and an improving economy.

# Is There an Operational Interest Rate Rule?

By MICHAEL DOTSEY\*

In his 1983 paper, Jeremy Siegel derives a seemingly implementable policy rule involving optimal responses to interest rates. The existence of such a rule would be of tremendous interest to central banks whose monetary policies place heavy weight on responses to interest rates. The Siegel rule is especially appealing because it is (i) an optimal combination policy in the sense of William Poole (1970), and (ii) the proposed implementation of the rule does not require detailed knowledge of the structure of the economy. All that is required is a calculation of the covariance between innovations in prices and interest rates.

Within the confines of a rational expectations equilibrium model, in which Siegel assumes agents do not make use of information embodied in the current nominal interest rate, he is able to design an optimal combination policy that does not require detailed information about the economy. That such an optimal policy exists is not new, but that it can be easily implemented is novel.<sup>1</sup> The policy rule depends solely on the covariance between innovations in the aggregate price level and innovations in the nominal rate of interest, normalized by the variance of innovations in the interest rate. When this index is zero, policy has been set optimally. When the index is positive the feedback term on interest rates in the money supply rule is too large, and when the index is negative the feedback term is too small. Given that one can obtain reduced-form expressions for prices and interest rates, the index is easily computed.

Unfortunately, Siegel's proposal violates Robert Lucas's (1976) critique. That is, he implicitly treats as invariant certain aspects of economic behavior that will generally change when one moves to an "operational interest rate rule." This note shows in detail that in a model where prices are flexible and agents observe local market prices (i.e., the model at least employed verbally by Siegel), that the coefficients in the aggregate supply and demand functions are not invariant to the form of the money supply rule. This lack of invariance will cause Siegel's rule to be nonoperational. The sensitivity of parameters in aggregate supply functions to policy is not restricted to equilibrium models with flexible prices. This property also extends to contracting models with endogenous indexing (see, for example, Jo Anna Gray, 1976). Therefore, Siegel's rule will not be implementable in a wide variety of commonly used macro models.

## I. Basic Micro Structure

In Siegel's model, agents form expectations conditioned on their observation of local prices. In this section a foundation consistent with the aggregate economy presented in Siegel is constructed. Let supply and demand in market  $z$  be represented by

$$(1) \quad y_t^s(z) = a_s(p_t(z) - E p_t | I_t(z)), \quad a_s > 0,$$

$$(2) \quad y_t^d(z) = a_d(r_t + p_t(z) - E p_{t+1} | I_t(z)) \\ + \varepsilon_t^d + z_t, \quad a_d < 0,$$

where  $y$  and  $p$  are logarithms of output and prices, and  $r$  is the nominal rate of interest. The letter  $z$  indicates the  $z$ th market and the notation  $E p_t | I_t(z)$  indicates the expectation of the log of the aggregate price level conditioned on current local information. This information is assumed to include the local price  $p_t(z)$ , past local and aggregate prices,

\*Federal Reserve Bank of Richmond, Richmond, VA 23261. I thank Marvin Goodfriend, Robert King, and Tony Kuprianov for helpful comments. The views expressed in this paper are not necessarily those of the Federal Reserve Bank of Richmond or the Federal Reserve System and are solely my responsibility.

<sup>1</sup>For example see Matthew Canzoneri et al. (1983), and Geoffrey Woglom (1979).

past interest rates, past levels of the money stock, and the values of all past disturbances. As in Siegel, the assumption that it is too costly for agents to process the information contained in the nominal interest rate is maintained.<sup>2</sup> The aggregate disturbance  $\varepsilon_t^A$  is a trendless random walk equal to  $\varepsilon_{t-1}^A + \tilde{\varepsilon}_t^A$ , while  $z_t$  is a local disturbance and is assumed to be white noise.

## II. The Macro Structure

Averaging across markets yields aggregate supply and demand curves similar to those presented by Siegel. (A lagged output term in (1') is omitted for simplicity.)

$$(1') \quad y_t^s = a_s(p_t - \overline{E}p_t|I_t(z)),$$

$$(2') \quad y_t^d = a_d(r_t + p_t - \overline{E}p_{t+1}|I_t(z)) + \varepsilon_t^A.$$

Here the overbar indicates the average of all local expectations and it is assumed that the relative disturbances cancel out across markets.<sup>3</sup>

The model is completed by appending Siegel's equation (3), which describes the money market:<sup>4</sup>

$$(3) \quad m_t = m_0 + m_r r_t = \bar{p}_t + l_y y_t + l_r r_t + \varepsilon_t^L, \\ l_y > 0, l_r < 0.$$

The log of money supplied,  $m_t$ , is determined by a combination policy and is equal to money demand. The disturbance term  $\varepsilon_t^L$  is also a trendless random walk depicted by  $\varepsilon_t^L = \varepsilon_{t-1}^L + \tilde{\varepsilon}_t^L$ .

<sup>2</sup>It is well known that if agents use the nominal interest rate, then interest rate feedback rules have no real effects. For a more detailed discussion of this point see my article with Robert King (1983), or Siegel. The assumption that agents do not use the information contained in the interest rate is employed in an effort to be consistent with the main elements of Siegel's analysis.

<sup>3</sup>The above aggregate supply and demand curves are similar to those derived by myself and King.

<sup>4</sup>For expositional ease it is assumed that the pure money stock component of the money supply rule is constant.

The analysis in Siegel proceeds by examining the innovations in prices and interest rates. For notational convenience, let a tilde over a variable indicate an innovation in that variable (i.e.,  $\tilde{x}_t = x_t - Ex_t|I_{t-1}^*$ ), and where  $I_{t-1}^*$  equals  $I_{t-1}(z)$  plus knowledge of  $\varepsilon_{t-1}^A$  and  $\varepsilon_{t-1}^L$ . However, before proceeding, terms such as  $\overline{E}p_t|I_t(z)$ , and  $\overline{E}p_{t+1}|I_t(z)$  must be analyzed.

## III. Expectations and Information

Equations (1'), (2'), and (3) present a model of an economy that is log linear. Therefore, one may postulate a linear solution for  $p_t(z)$ ,  $p_t(z) = \pi_1 m_0 + \pi_2 \varepsilon_{t-1}^A + \pi_3 \varepsilon_{t-1}^L + \pi_4 z_t + \pi_5 \tilde{\varepsilon}_t^A + \pi_6 \tilde{\varepsilon}_t^L$ . The expectations of the aggregate price level and next period's price level can be determined by the following equations:<sup>5</sup>

$$(4a) \quad Ep_t|I_t(z) = Ep_t|I_{t-1}^* \\ + \beta(p_t(z) - Ep_t|I_{t-1}^*),$$

$$(4b) \quad \overline{E}p_t|I_t(z) = Ep_t|I_{t-1}^* \\ + \beta(p_t - Ep_t|I_{t-1}^*),$$

$$(5a) \quad Ep_{t+1}|I_t(z) = Ep_{t+1}|I_{t-1}^* \\ + \gamma(p_t(z) - Ep_t|I_{t-1}^*),$$

$$(5b) \quad \overline{E}p_{t+1}|I_t(z) = Ep_{t+1}|I_{t-1}^* \\ + \gamma(p_t - Ep_t|I_{t-1}^*).$$

In the above expressions,  $Ep_t|I_{t-1}^* = \pi_1 m_0 + \pi_2 \varepsilon_{t-1}^A + \pi_3 \varepsilon_{t-1}^L = Ep_{t+1}|I_{t-1}^*$ . Using equations (1') and (2'), along with (4b) and (5b), the aggregate supply and demand curves can be expressed as

$$(1'') \quad y_t^s = a_s(1 - \beta)(p_t - Ep_t|I_{t-1}^*),$$

$$(2'') \quad y_t^d = a_d[r_t + p_t - Ep_{t+1}|I_{t-1}^* \\ - \gamma(p_t - Ep_t|I_{t-1}^*)] + \varepsilon_t^A.$$

<sup>5</sup>For more detail, see my article with King, or Thomas Sargent (1979).

Notice that the elasticities of supply and demand are not independent of policy parameters, since the regression coefficients  $\beta$  and  $\gamma$  are composed of all the underlying parameters of the model as well as the variances and covariances of the disturbance terms. This observation represents the essential difference between the model presented in Siegel and the one derived here. Of crucial importance is that this model is derived from the underlying equilibrium conditions in local markets and is therefore consistent with the description of the economy advanced by Siegel.

#### IV. Siegel's Index

The derivation of Siegel's index proceeds from an examination of the innovations in prices and interest rates. Using (1''), (2''), and (3) these may be expressed as

$$(6) \quad \tilde{y}_t = a_s(1-\beta)\tilde{p}_t,$$

$$(7) \quad \tilde{r}_t = - \left[ [1 + l_y a_s(1-\beta)] \tilde{\epsilon}_t^A + [a_s(1-\beta) - a_d(1-\gamma)] \tilde{\epsilon}_t^L \right] / \left[ [a_s(1-\beta) - a_d(1-\gamma)] [l_r - m_r] + a_d[1 + l_y a_s(1-\beta)] \right],$$

$$(8) \quad \tilde{p}_t = \left[ (l_r - m_r) \tilde{\epsilon}_t^A - a_d \tilde{\epsilon}_t^L \right] / \left[ [a_s(1-\beta) - a_d(1-\gamma)] [l_r - m_r] + a_d[1 + l_y a_s(1-\beta)] \right].$$

These latter three expressions are analogous to Siegel's equations (4)–(6), and would be identical if  $\beta = 0$  and  $\gamma = 1$ . This last condition is impossible given the derivations for  $\beta$  and  $\gamma$ .<sup>6</sup>

The goal of monetary policy is to minimize the variance of output around its full-

information value, which in Siegel's context is equivalent to minimizing  $\sigma_p^2$ .<sup>7</sup> This is done by choosing the appropriate value of  $m_r$ , call it  $m_r^*$ . One can also find the value of  $m_r$ , call it  $\hat{m}_r$ , that forces the  $\text{cov}(\tilde{p}, \tilde{r}) = 0$ . In Siegel's model, it turns out that these two values of  $m_r$  are the same (i.e.,  $m_r^* = \hat{m}_r$ ), and that a monetary policy which sets  $\text{cov}(\tilde{p}, \tilde{r}) = 0$  is optimal. Here it can be shown that unless  $\partial\beta/\partial m_r = \partial\gamma/\partial m_r = 0$  when evaluated at  $\hat{m}_r$ , that this is not the case. Therefore, the optimal value of this covariance will end up being a complicated function of the parameters of the model, and Siegel's procedure does not represent an improvement on existing literature.

To see that this is true, it is necessary to carefully examine the expressions for  $\beta$  and  $\gamma$ , as well as the  $\text{cov}(\tilde{p}, \tilde{r})$ . In the following analysis it is assumed that all the disturbances are independent. Using the undetermined coefficients solution for  $p_t(z)$ ,  $\beta$  and  $\gamma$  can be expressed as

$$\beta = \frac{\pi_5^2 \sigma_A^2 + \pi_6^2 \sigma_L^2}{\pi_4^2 \sigma_z^2 + \pi_5^2 \sigma_A^2 + \pi_6^2 \sigma_L^2},$$

$$\gamma = \frac{\pi_2 \pi_5 \sigma_A^2 + \pi_3 \pi_6 \sigma_L^2}{\pi_4^2 \sigma_z^2 + \pi_5^2 \sigma_A^2 + \pi_6^2 \sigma_L^2},$$

where  $\sigma_z^2$ ,  $\sigma_A^2$ , and  $\sigma_L^2$  are the variances of  $z$ ,  $\tilde{\epsilon}^A$ , and  $\tilde{\epsilon}^L$ , respectively. Using the solutions for the  $\pi$ 's, these expressions can be manipulated to yield

$$(9) \quad \beta = \left[ [a_s(1-\beta) - a_d(1-\gamma)]^2 \times [(l_r - m_r)^2 \sigma_A^2 + a_d^2 \sigma_L^2] \right] / \left[ \delta^2 \sigma_z^2 + [a_s(1-\beta) - a_d(1-\gamma)]^2 \times [(l_r + m_r)^2 \sigma_A^2 + a_d^2 \sigma_L^2] \right],$$

$$(10) \quad \gamma = \delta\beta/a_d,$$

<sup>6</sup>If Siegel had postulated an aggregate demand function of the form  $y_t^d = a_d(r_t + p_t - \bar{E}p_{t+1}) + \epsilon_t^A$ , then our results would be identical with  $\beta = \gamma = 0$ .

<sup>7</sup>Since  $\beta$  is now a function of  $m_r$ , this is no longer the case. Also, Robert Barro (1976) makes an appealing case for minimizing the variance of local output around its full-information value. This policy is also not equivalent to the one used by Siegel.

where  $\delta = [a_s(1-\beta) - a_d(1-\gamma)][l_r - m_r] + a_d[1 + l_y a_s(1-\beta)]$ . It is clear that  $0 \leq \beta \leq 1$  and  $\beta \rightarrow 0$  as  $\sigma_z^2 \rightarrow \infty$ , and that  $\beta \rightarrow 1$  as  $\sigma_z^2 \rightarrow 0$ . The  $\text{cov}(\tilde{p}, \tilde{r})$  is given by

$$(11) \quad \text{cov}(\tilde{p}, \tilde{r}) = [a_d[a_s(1-\beta) - a_d(1-\gamma)]\sigma_L^2 - [l_r - m_r][1 + l_y a_s(1-\beta)]\sigma_A^2] / \delta^2.$$

The expressions for  $\beta$ ,  $\gamma$ , and  $\delta$  will now be analyzed to show that setting the  $\text{cov}(\tilde{p}, \tilde{r}) = 0$  is not in general optimal. First observe that the value of  $m_r$  which sets  $\text{cov}(p, r) = 0$  is given by

$$\hat{m}_r = l_r - [a_d[a_s(1-\beta) - a_d(1-\gamma)]\sigma_L^2] / [1 + l_y a_s(1-\beta)]\sigma_A^2.$$

Also, using (8) it can be shown that the optimal value of  $m_r$ ,  $m_r^*$ , satisfies the following equation:

$$(12) \quad (l_r - m_r)\delta^2\sigma_A^2 + \delta[(l_r - m_r)^2\sigma_A^2 + a_d^2\sigma_L^2](\partial\delta/\partial m_r) = 0.$$

The value of  $m_r$  that satisfies (12) will equal  $\hat{m}_r$  if and only if  $\partial\beta/\partial m_r = \partial\gamma/\partial m_r = 0$  at  $\hat{m}_r$ . In the Appendix, this is shown not to be generally true. It will, however, be true in the case where  $\sigma_z^2 = \infty$ , because this implies that agents will not use any local information in forming expectations. Therefore, the aggregate supply and demand elasticities will not be influenced by changes in policy, since it was only through the expectation-generating process that policy parameters influenced these elasticities.

Since  $m_r^* \neq \hat{m}_r$ , the  $\text{cov}(\tilde{p}, \tilde{r})$  evaluated at  $m_r^*$  will involve all the parameters and variances of the model including the coefficients  $\beta$  and  $\gamma$ . Therefore, the monetary authority could not use the zero covariance criterion to choose  $m_r^*$ . Further, the index derived by Siegel that allows for unambiguously correct movements in policy when the  $\text{cov}(\tilde{p}, \tilde{r})$  strays from zero ought to be monotonic in  $m_r$ . Given that this index will involve the expression for  $\beta$  and  $\gamma$ , it is not clear that

this condition will be met. In short, there is no easy way of implementing a combination policy within the framework envisioned by Siegel.

## V. The Problem Extended to Contracting Models

The problems inherent in implementing Siegel's interest rate rule have been discussed in detail within the context of a model where local information is important. However, similar types of problems will occur in contracting models where wages are preset and the contracts involve endogenous indexing (see Gray).<sup>8</sup> The primary reasons for this are (i) that aggregate supply responses depend upon the optimal degree of wage indexation, and (ii) that the degree of wage indexation is sensitive to policy. Therefore the responsiveness of aggregate supply to movements in prices from their expected value, the expectation being conditioned on last period's information, is sensitive to policy.<sup>9</sup> Equivalently, this means that the coefficient in the aggregate supply schedule is not invariant to policy choices. It is this lack of invariance that will produce problems similar to those outlined above.

## VI. Conclusions

This note has shown that one can generally expect the coefficients in an aggregate supply function to be sensitive to monetary policy. This lack of policy invariance is in agreement with the Lucas critique. Importantly, it provides the mechanism that renders Siegel's interest rate rule nonoperational. For Siegel to make his proposal attractive, he must first derive supply and demand schedules that are invariant to his policy rule. Since a large class of currently used models do not display this behavior, any results along this line are of limited interest.

<sup>8</sup> Gray's model does not involve interest rates. I have worked out the results involving feedback terms on prices. The basic argument should not be sensitive to the particular variable to which monetary policy responds.

<sup>9</sup> Note in Gray's model, the certainty equivalent level of prices,  $p_t^*$ , and  $E_{t-1} p_t$  are equivalent.

## APPENDIX

This Appendix evaluates the derivatives of  $\partial\beta/\partial m_r$  and  $\partial\gamma/\partial m_r$ , by using the implicit function theorem. Using the derivations of  $\beta$ ,  $\gamma$ , and  $\delta$ , define the following system of implicit functions:

$$(A1) \quad 0 = F(\beta, \gamma, \delta; m_r, \dots)$$

$$\begin{aligned} &= \beta - [a_s(1-\beta) - a_d(1-\gamma)]^2 \\ &\quad \times [(l_r - m_r)^2 \sigma_A^2 + a_d^2 \sigma_L^2] \\ & / [\delta^2 \sigma_z^2 + [a_s(1-\beta) - a_d(1-\gamma)]^2 \\ &\quad \times [(l_r - m_r)^2 \sigma_A^2 + a_d^2 \sigma_L^2]] \end{aligned}$$

$$(A2) \quad 0 = G(\beta, \gamma, \delta; m_r, \dots) \equiv \gamma - \delta\beta/a_d,$$

$$\begin{aligned} (A3) \quad 0 &= H(\beta, \gamma, \delta; m_r, \dots) \\ &= \delta - [a_s(1-\beta) - a_d(1-\gamma)][l_r - m_r] \\ &\quad - a_d[1 + l_y a_s(1-\beta)]. \end{aligned}$$

Differentiating this system yields

$$\begin{bmatrix} F_\beta & F_\gamma & F_\delta \\ G_\beta & G_\gamma & G_\delta \\ H_\beta & H_\gamma & H_\delta \end{bmatrix} \begin{bmatrix} \partial\beta/\partial m_r \\ \partial\gamma/\partial m_r \\ \partial\delta/\partial m_r \end{bmatrix} = \begin{bmatrix} -F_{m_r} \\ -G_{m_r} \\ -H_{m_r} \end{bmatrix}.$$

It can be shown that  $\partial\beta/\partial m_r = 0$  when

$$\begin{aligned} m_r &= l_r - [\{a_d[a_s(1-\beta) - a_d(1-\gamma)] \\ &\quad + a_d^2\beta[1 + l_y a_s(1-\beta)]\} \sigma_L^2] \\ &\quad / \{[1 + l_y a_s(1-\beta)] \sigma_A^2 \\ &\quad + a_d\beta[a_s(1-\beta) - a_d(1-\gamma)] \sigma_L^2\}. \end{aligned}$$

This will be equivalent to  $\hat{m}_r$  when  $\beta = 0$ , which occurs when  $\sigma_z^2 = \infty$ . One can also use the derivation of  $\gamma$  to observe that  $\partial\gamma/\partial m_r$

$= (\delta\partial\beta)/(\sigma_A^2\partial m_r) + (\beta\partial\delta)/(\sigma_L^2\partial m_r)$ . Evaluating this at  $m_r = \hat{m}_r$  and  $\sigma_z^2 = \infty$  implies that  $\partial\gamma/\partial m_r = 0$ . Therefore, when  $\sigma_z^2 = \infty$ ,  $\partial\beta/\partial m_r = \partial\gamma/\partial m_r = 0$  at  $\hat{m}_r$ , and  $\hat{m}_r = m_r^*$ . However, in general  $\partial\beta/\partial m_r$  and  $\partial\gamma/\partial m_r$  do not equal zero when evaluated at  $m_r$ , implying that  $\hat{m}_r \neq m_r^*$ .

## U.S. Monetary Policy and the Exchange Rate: Comment

By STEVEN AMBLER AND RONALD MCKINNON\*

In the March 1984 issue of this *Review*, Henry Goldstein and Stephen Haynes were sharply critical of Ronald McKinnon's (1982) analysis of how the foreign exchanges impinge on the American monetary system. McKinnon contends that central banks in open economies should take pressure in the foreign exchanges into account in formulating domestic monetary policy. Money growth should be higher than normal when the domestic currency tends to appreciate against "hard" foreign monies, and vice versa. By following such a rule, the authorities in any industrial economy (including the United States) can better balance the supply to the (international) demand for the national money so as to prevent unexpected inflations or deflations.

Somewhat strangely, Goldstein-Haynes first try to reject McKinnon's idea that shifts in international portfolio preferences indirectly destabilize the demand for domestic money. Then they go on to propose an "alternative" view that governments often intervene to stabilize their foreign exchange rates, allowing domestic money growth to vary in support, as a means of stabilizing the domestic price level. They cite approvingly the unusually high money growth in Germany in 1977-78, when the foreign exchange value of the deutsche mark was increasing sharply. But this is not an alternative view at all! It is McKinnon's view of how the central bank should respond to a signal from the foreign exchanges in order to prevent sudden exchange overvaluation and deflation.

Indeed, McKinnon criticized the failure of the U.S. Federal Reserve System to respond properly to large fluctuations in the dollar exchange rate from 1970 to mid-1982 when other industrial countries were intervening

—not very successfully—to smooth their exchange rates. The resulting cyclical fluctuations in the rest of the world's money *and* in the dollar exchange rate then fed back into sharp cycles of inflation and deflation within the United States itself.

Let us now turn to Goldstein and Haynes' empirical work measuring international influences on the American economy. The potential importance of the exchange rate was established in the econometric interchange among McKinnon, Christopher Radcliffe, Kong-Yam Tan, Arthur Warga, and Thomas Willett in the December 1984 issue of this *Review*. Fluctuations in the dollar exchange rate appear to be an important leading indicator of subsequent changes in American nominal *GNP* and in the dollar prices of tradable goods—for which estimates are more fully worked out in McKinnon (1984) and Tan (1984).

In contrast, Goldstein and Haynes omitted the dollar exchange rate from their empirical analysis and thus failed to come to grips with this important part of the McKinnon hypothesis. We would welcome further empirical work where they included the (lagged) dollar exchange rate as an explanatory variable in their St. Louis regressions. If floating was "clean," the exchange rate would be a sufficient statistic to measure (indirect) fluctuations in the demand for money in the United States.

Under the world dollar standard and "dirty" floating, however, foreign central banks continually intervene to (partially) stabilize their dollar exchange rates. Consequently, portfolio shifts for or against dollar assets—mainly bonds—can lead to changes in foreign money growth rates which also reflect changes in money market conditions in the United States (McKinnon, 1982). In addition, foreign money growth could well have an independent effect on the dollar prices of American tradable goods. To test this aspect of the McKinnon hypothesis,

\*Department of Economics, Stanford University, Stanford, CA 94305.

Goldstein and Haynes regress U.S. price changes on U.S. and foreign money growth rates. They find that foreign money is not statistically significant. Even here, however, their statistical procedures are inappropriate.

First, McKinnon states that "wholesale indices come closer than consumer prices to provide a common denominator of tradable goods" (1982, p. 332). Somewhat inexplicably, Goldstein and Haynes use instead the U.S. GNP deflator as their dependent variable without warning the reader that they had changed price indices from those McKinnon had originally used. The GNP deflator contains large nontradable components—mainly services—which are less sensitive to foreign influences. In contrast, foreign money growth does have a significant impact on American wholesale (producer) prices, as indicated in the preceding interchange.

Precisely which price index the central bank should aim to stabilize is an open question. A case can be made for focusing on a broad commodities index from which changes in the cost of services, most of which are impossible to measure accurately, are omitted. This case is made even stronger if exchange rate stabilization among hard-currency countries, with similar price objectives, is deemed desirable.

Second, by using twelve-quarter moving averages for their explanatory monetary variables, Goldstein and Haynes tend to suppress—or smooth out—the sharp cyclical fluctuations of one to two years in "world" money growth with which McKinnon was so concerned. Their statistical regression procedures were not set up correctly to test the McKinnon hypothesis.

From our experience so far with floating exchange rates in the 1970's and 1980's, how can we best summarize the impact of the foreign exchanges on the American monetary system? Because of lags in the collection of data on both foreign and American money supplies, the dollar exchange rate is the more immediately relevant leading indicator of inflation or deflation to come in the American economy. In the intermediate run, however, growth in foreign hard monies should be monitored by the Federal Reserve in order to prevent undue expansion or contraction in

the joint monetary base of the system as a whole.

By this international standard, how well has the Fed done in 1984? Unfortunately the Fed erred by keeping U.S. M1 growth at a normal annual rate of 5 to 6 percent *despite* the further sharp appreciation of the dollar exchange rate from a level which was already grossly overvalued. This international portfolio shift in favor of a broad spectrum of dollar assets signalled that 1) the derived demand for U.S. base money had increased, and 2) that the brunt of the resulting deflationary pressure in 1985 would be borne by American export and import-competing industries—resulting in a further upsurge of protectionist sentiment in the United States.

What about growth in "world" money in the first nine months of 1984? To prevent their currencies from depreciating even further against the dollar and provoke more protectionism in the United States, both the German Bundesbank and the Bank of Japan were forced to curtail growth in their own M1s below normal. Consequently joint money growth in the three countries was too low, and reinforced the signal given by the appreciating dollar of too much deflationary pressure—with the risk of an unnecessary cyclical downturn in the United States (and elsewhere) in 1985.

Goldstein and Haynes fail to understand that, in a world where financial markets are integrated, only the strong-currency country (in 1984, the United States) has the option of expanding its money supply without throwing exchange rates further out of alignment, and threatening a breakdown of the international payments mechanism. Whence the need for explicit or implicit monetary coordination among the world's principal central banks.

# U.S. Monetary Policy and the Exchange Rate: Reply

By HENRY N. GOLDSTEIN AND STEPHEN E. HAYNES\*

In our earlier note (1984), we challenge the view of Ronald McKinnon (1982) that changes in rest-of-world money have had a dominant impact on U.S. inflation and output over the last decade because of indirect currency substitution (*ICS*). Steven Ambler and McKinnon (1985) disagree, modifying the *ICS* model by introducing the exchange rate as an additional indicator of foreign monetary policy. In this reply, we again conclude that no convincing evidence exists to support *ICS* for the United States over the past decade.

We make the following points to Ambler and McKinnon.

1. We agree that lagged growth rates in rest-of-world money tend to explain movements in the U.S. *WPI* better than they explain movements in the U.S. *GNP* deflator. But the *WPI*, which weights heavily the tradeable goods sector, is a less significant policy target than the *GNP* deflator, which represents the price of domestic output. And, as we have shown, the *GNP* deflator is much more sensitive to domestic money growth than to external money growth. Accordingly, we remain skeptical about McKinnon's recommendation that the U.S. authorities should give rest-of-world money a significant weight in formulating their monetary policy. Nor do we view the relatively high sensitivity of the *WPI* to changes in rest-of-world money as supporting the pervasiveness of *ICS* rather than simply the existence of traditional open economy interdependence. Although *ICS* links economies through capital arbitrage effects on interest rates and money demand,

the elasticities approach links economies directly through the tradeable goods sector.<sup>1</sup>

2. Ambler and McKinnon argue that our twelve-quarter moving averages used for the money variables tend to suppress the cyclical (one to two-year) movements with which McKinnon was concerned. However, as we stated earlier (p. 222), reestimation after expressing the money variables in distributed lags rather than moving averages still shows that rest-of-world money plays at best a minor role in influencing the U.S. *GNP* deflator. We conclude that the moving averages do not merely reflect secular or trend effects.

3. We agree that lagged exchange rates when added to our simple St. Louis model tend to influence the U.S. price level with the correct sign.<sup>2</sup> But the domestic price level and the exchange rate are necessarily linked whenever domestic residents consume foreign goods and domestic products compete against actual or potential imports. Given these obvious conditions, we fail to see how verification of a statistical linkage between the domestic price level and the exchange rate lends special support to McKinnon's view of the world as opposed to any other.

4. As noted by A. H. Meltzer (1984), McKinnon's policy recommendation regarding the exchange rate could lead to unfortunate

\*Department of Economics, University of Oregon, Eugene, OR 97403-1202. We thank Randy Eberts, Michael Hutchison, Joe Stone, and Bob Traa for helpful comments.

<sup>1</sup>Also see M. S. Wallace (1984) regarding the sensitivity of various U.S. price indexes to movements in U.S. (world) money.

<sup>2</sup>The coefficients on the lagged exchange rates are generally significant if the contemporaneous exchange rate is included in the equation, but insignificant if the contemporaneous exchange rate is excluded from the equation. Since the U.S. price level no doubt influences the exchange rate contemporaneously, estimates with the contemporaneous exchange rate on the right-hand side reflect simultaneous equation bias.

results in certain circumstances. During 1983-84, for example, the dollar appreciated against the deutsche mark even though economic growth in the United States was stronger than in West Germany. McKinnon's formula would presumably have favored faster monetary growth in the United States than actually prevailed, and slower monetary growth in West Germany. Given the evidence that domestic money affects domestic prices and activity more strongly than external money (see our earlier paper and F. Spinelli, 1983), this formula could well have tended to overheat the U.S. economy and retard desirable expansion in West Germany.

In summary, we continue to find no convincing evidence that the recent sharp cycles of inflation and deflation experienced by the United States since 1970 as well as the recent real growth with much reduced inflation can be explained exclusively, or even largely, by McKinnon's model of indirect currency substitution. We still view exogenous real shocks and swings in domestic monetary and fiscal policies as the major determinants of U.S. inflation and output.

# The Money Supply Announcements Puzzle: Comment

By BARRY FALK AND PETER F. ORAZEM\*

In a recent paper in this *Review* (1983), Bradford Cornell presented a survey of existing literature on the empirical relationship between weekly money supply announcements made by the Federal Reserve and changes in the spot prices of several financial instruments at the time of the announcement. Cornell sought to unify and extend the work done in this area by estimating a number of relationships which bear directly on this issue. Among his main conclusions are that "asset markets are efficient with respect to money supply announcements" since "only the unexpected component of the announcement is correlated with price changes," and that the unexpected component of money supply announcements has "a highly significant positive correlation" with short-term interest rates, but only after the October 6, 1979 change in Fed policy (p. 651). Both of these conclusions are at variance with results reported in similar studies by Jacob Grossman (1981), V. Vance Roley (1982), and Thomas Ulrich and Paul Wachtel (1981). All three find that unanticipated announcements matter in periods before October 6, 1979, and Roley and Ulrich-Wachtel find that anticipated announcements matter in at least some of their regressions.

The main difference between Cornell's study and those mentioned above is that more exact measures of the change in short-term interest rates are used in the latter studies. Since the money supply announcements are made at 4:00 P.M., Cornell uses the change in the yield on three-month Treasury bills from 3:30 P.M. on the day of the announcement to 3:30 P.M. on the day after the announcement. Ulrich-Wachtel consider Treasury bill yield changes from 3:30 P.M. on the day of the announcement to 10:30 A.M. the next day. Grossman and Roley further refine the measure by looking at yield changes from 3:30 to 5:00 on the day of the announcement.

While the different measure of changes in the short-term interest rates might account for the inconsistencies between Cornell's study and earlier studies, the inconsistencies are still surprising. Undoubtedly, Cornell's measure of Treasury bill yield changes includes fluctuations in interest rates caused by new information on the day after the announcement. However, to the extent that markets function efficiently, only unexpected information should cause these additional interest rate movements. Because this unexpected information must be uncorrelated with past information, Cornell's estimates should be consistent and unbiased. Thus, it is puzzling that Cornell's results differ so drastically with the earlier studies.

This comment indicates that the inconsistencies are not attributable to differences in measures of short-term interest rate changes. Using essentially the same data and methods as Cornell, we obtain results that are more in line with the earlier studies. Below we briefly summarize the data and methodology and then contrast our results to those Cornell reported.

Like Cornell, we used the median value of the weekly Money Market Services survey for  $M1$  as our measure of the anticipated component of the announcement ( $EM_t$ ) and the difference between the actual announcement and its anticipated value as our measure of the unanticipated component of the announcement ( $UM_t$ ).<sup>1</sup> The immediate re-

<sup>1</sup>The Money Market Services data associate the anticipated announcement with the week to which the announcement actually pertains. Thus, for example, a money supply announcement made on Thursday, April 19, 1984, would be listed under "Statement Week April 9, 1984." We would look at the change in the Treasury bill rate from the close on the 19th to the close on the 20th as the response to this announcement. When the Fed's announcement occurs on a Friday, we consider the difference between the Friday close and the Monday close. More generally, we looked at the close on the first market-operating day after the announcement minus the close on the day of the announcement.

TABLE 1—SUMMARY STATISTICS

	Mean	Standard Deviation
Sample Period: January 5, 1978–October 4, 1979		
Cornell		
EM	0.12	0.45
UM	0.20	0.35
DTB	2.58	10.61
Falk-Orazem		
EM	0.21	0.35
UM	-0.12	0.44
DTB	2.81	10.48
Sample Period: October 11, 1979–December 18, 1981		
Cornell		
EM	0.06	0.26
UM	-0.04	0.58
DTB	8.68	40.80
Falk-Orazem		
EM	0.07	0.26
UM	0.04	0.54
DTB	6.46	40.66

Notes: UM = The unexpected component of the money supply announcement in percentage change in the money supply; EM = the anticipated component of the money supply announcement in percentage change in the money supply; DTB = the change from the close before the money supply announcement to the close after the announcement of the yield on the latest three-month Treasury bill in basis points.

sponse of the three-month Treasury-bill yield ( $DTB_t$ ) was measured as the difference in the 3:30 closing yield on the day of the announcement and the 3:30 close on the following (market) day. Summary statistics for our data and Cornell's (p. 650) are presented in Table 1.

If one reverses the line corresponding to anticipated and unanticipated money supply announcements for the first sample period in Cornell's summary, then our data on the money supply are virtually identical except for the sign differences on UM (which we computed by subtracting EM from the actual announcement). The standard deviations on the Treasury bill rate changes are nearly identical although our mean values differ somewhat. Since our data sources are identical and we thoroughly hand-checked our punched data against the original sources, we suspect that Cornell's sample mean for DTB during the second sample period should probably read "6," rather than "8."

To estimate the effect of the money supply announcement on the three-month Treasury

bill yield, Cornell regressed  $DTB_t$  on  $EM_t$ ,  $UM_t$ , and a constant for each of the two sample periods. We did likewise. The results from our regressions are compared to Cornell's (p. 651) in Table 2. Our fits (as measured by the  $R^2$ ) are substantially higher than those Cornell reports for both sample periods. We found that unanticipated money supply changes have a significant positive effect over both sample periods and anticipated money supply changes have a significant negative effect during the second sample period. The only significant coefficient Cornell found was the coefficient on unanticipated money over the second sample period.

Roley found that over the period September 9, 1977–October 4, 1979, unanticipated money supply changes had a significantly positive effect on Treasury bill yields while anticipated money supply changes had a negative, but not significant effect. This result persisted over the sample period October 11, 1979–January 31, 1980. Over the sample period February 8, 1980–November 20, 1981, Roley found both anticipated and unanticipated money supply announcements to have significant negative and positive effects, respectively.<sup>2</sup> Thus Roley's results look very much like our own.<sup>3</sup>

We are led to conclude that the results reported by Cornell regarding the effects of anticipated and unanticipated money supply

<sup>2</sup>Roley obtained the following results:

Sample period: September 29, 1977–October 4, 1979

$$DTB = -0.0027 + 0.0065 UM_t - 0.0014 EM_t, R^2 = .05$$

(0.0045) (0.0025) (0.0031)

Sample period: October 11, 1979–January 31, 1980

$$DTB = 0.0014 + 0.0510 UM_t - 0.0070 EM_t, R^2 = .34$$

(0.0205) (0.0161) (0.0223)

Sample period: February 8, 1980–November 20, 1981

$$DTB = 0.0160 + 0.0657 UM_t - 0.0531 EM_t, R^2 = .34$$

(0.0230) (0.0096) (0.0210)

(Standard errors are in parentheses.) Roley measures  $UM_t$  and  $EM_t$  in terms of the change in the money supply in billions of dollars.

<sup>3</sup>Estimates by Grossman and Urlich-Wachtel over the pre-October 6, 1979 sample period are also similar to ours, i.e., they obtain positive coefficients on unanticipated announcements and negative coefficients on anticipated announcements.

TABLE 2—REGRESSION COMPARISONS<sup>a</sup>  
 $DTB_t = a_0 + a_1 UM_t + a_2 EM_t + U_t$

	$a_0$	$a_1$	$a_2$	$R^2$

Cornell	2.30 (1.72)	1.92 (0.77)	0.24 (0.07)	.063
Falk-Orazem	4.66 (3.62)	7.09 (2.93)	-4.64 (-1.53)	.104
Sample period: October 11, 1979–December 18, 1981				
Cornell	7.21 (1.97)	30.46 (4.33)	-5.36 (-0.35)	.234
Falk-Orazem	6.75 (2.03)	41.83 (6.90)	-27.37 (-2.16)	.303

Notes: See Table 1.

<sup>a</sup>t-statistics are shown in parentheses.

announcements on the price of Treasury bill yields are incorrect quantitatively and qualitatively. Furthermore, we find that the measured response of short-term interest rates to money supply announcements are robust to slight changes in the measurement of the interest rate changes. Our results suggest that studies of money supply announcement effects are not as sensitive to the specification of Treasury bill rate changes as Cornell's results would suggest.

# The Money Supply Announcements Puzzle: Reply

By BRADFORD CORNELL\*

I thank Barry Falk and Peter Orazem for the comment on my 1983 paper. In response to their work I hand-checked my data using independent sources and found several errors. Initially I used a time-series of survey forecasts and forecast errors provided by Money Market Services. Though the survey data was correct, the reported forecast errors, in several instances, were based on incorrect numbers for the actual change in the money supply.

The main effect of these errors is to change the regression coefficients reported in Table 3 of my paper. For this reason a revised version of Table 3 (see Table 1) is presented here. The coefficients in the revised table are

very similar, but not identical, to those reported by Falk and Orazem. The remaining differences must be due to the fact that the interest data are not identical.

The only substantive change in the results is that expected money is now significant for long-term bonds in the post-October 6 sample, and nearly significant for short-term bills in both sample periods. This is more consistent with the findings of Falk and Orazem and the earlier work of Jacob Grossman (1981), V. Vance Roley (1982), and Thomas Ulrich and Paul Wachtel (1981).

Finally, Falk and Orazem are also correct in noting a typographical error in Table 2 of my earlier paper. The standard deviation of

# Fisher's Paradox: Comment

By PATRICK HONOHAN\*

In a recent paper in this *Review* (1983), Jeffrey Carmichael and Peter Stebbing (C-S) examine the correlation between after-tax interest rates and the expected inflation rate. They contrast the Fisher hypothesis, that nominal interest rates move in line with expected inflation, with their own "inverted Fisher hypothesis," that nominal interest rates (on financial assets) are uncorrelated with expected inflation.

The main evidence adduced by C-S is a regression equation relating changes in interest rates to subsequent changes in the rate of inflation. Their equation can, with some manipulation, be rewritten in the simple form:

$$(1) \quad i_t - i_{t-1} = \alpha(\pi_t - \pi_{t-1}) + u_t,$$

where  $i_t$  is the nominal after-tax return on Treasury bills, and  $\pi_t$  is the rate of *CPI* inflation in the quarter after the observation of  $i_t$ . For both the United States and Australia, the coefficient  $\alpha$  is estimated not to be significantly different from zero. For instance, their equation 1.B (Table 1, p. 624) can be rewritten as

$$(2) \quad i_t - i_{t-1} = \frac{-0.024}{(T=1.1)} (\pi_t - \pi_{t-1})$$

(U.S., 1953:I–1978:IV,  $D-W=1.92$ .)

In these equations, the rate of inflation is thought of as a proxy for the expected rate of inflation. A natural reaction would be to conclude that the change in subsequent inflation has turned out to be a rather poor proxy for the change in expected inflation. However, C-S claim that the errors-in-variables bias in the estimate of  $\alpha$  is small, even under the Fisher hypothesis of  $\alpha=1$ .

In order to obtain an estimate of this bias, C-S assume that changes in inflation are truly a first-order moving average process, and that inflationary expectations are optimal forecasts relative to that process. Using conventional assumptions concerning the disturbance  $u_t$ , they arrive at a figure of  $-0.12$  for the bias in the estimate of  $\alpha$ . Unfortunately, this figure would only be correct for a regression based on the explanatory variable being in levels, whereas their equation in fact has first differences.<sup>1</sup>

The asymptotic bias for first differences is much larger. It is easy to see why: using actual inflation as a proxy for expected inflation involves an error whose variance is small relative to the variance of expected inflation. But the *change* in expected inflation is a rather smooth series by comparison with the change in actual inflation, so using the change in actual inflation as a proxy for the change in expected inflation involves an error whose variance is large relative to the variance of the change in expected inflation.

If we implement the general approach of C-S for the first difference of inflation, we find the much higher figure of about  $-0.85$  for the bias<sup>2</sup> (under the Fisher hypothesis). Of course, this would bring the point esti-

<sup>1</sup>Some other equations are in levels, but with correction for high positive first-order autocorrelation coefficients, leading to essentially the same problem with the calculation of bias as I outline here.

<sup>2</sup>Assuming that the first-order moving average parameter in the process generating expected inflation is about  $-0.75$ , and working in logs rather than levels as C-S do. There is little to choose between the logs and levels specification and only the log specification allows an analytic expression for the bias. In correspondence, Carmichael has stressed that my estimate of  $-0.85$  requires the usual assumption of no correlation between the (change in) true expected inflation series and the disturbance term. If this assumption is not valid, then not only might the bias be even greater, but the whole C-S approach, including their equation 1.G (Table 1) is marred by the inconsistency of *LS* estimators in the absence of this assumption.

\*Economic Adviser to the Taoiseach, Government Buildings, Dublin 2, Ireland. I am indebted to M. J. Harrison and L. O'Reilly for helpful comments.

mate of  $\alpha$  close to unity—the Fisher value.<sup>3</sup> Thus the equations reported by C-S could be read as broadly consistent with either the Fisher or the inverted Fisher hypothesis (if  $\alpha$  is truly zero, the bias is zero). Therefore we cannot take these equations as serious tests of either hypothesis.

Those who are not inclined to believe the inverted Fisher hypothesis may suspect that the bias is even greater than computed above. For one thing, working in first differences of inflation rates makes the choice of price index of primary importance. If the *CPI* were not exactly the index relevant to this Fisherian literature, and to the demand for Treasury bills, then its use as a proxy for inflationary expectations in this context would certainly be misleading. Changes in *CPI* inflation are only weakly (U.S.) or even

negatively (Australia) correlated with, for example, changes in producer price inflation. The above approach to the calculation of bias would not do where changes in the proxy variable were uncorrelated with the true but unobserved expectations variable, and in that case the expected value for the estimated coefficient  $\alpha$  would be zero.

One may also question the theoretical rationale given by C-S for their inverted Fisher theory. They argue convincingly that there is a high degree of substitutability between money and other financial assets. But they then infer that the implicit rate of return on holding money will be almost independent of the expected rate of inflation. This need only be so if the real stock of money were independent of the expected rate of inflation. This is not likely on theoretical or empirical grounds.

#### REFERENCE

<sup>3</sup>A referee has pointed out that in a market with rational inflation expectations, forecast errors will be serially uncorrelated. This would have the implication that, if expected inflation is highly positively autocorrelated, then the bias approaches  $-1$ .

Carmichael, Jeffrey and Stebbing, Peter W., "Fisher's Paradox and the Theory of Interest," *American Economic Review*, September 1983, 73, 619–30.

## Fisher's Paradox: Reply

By JEFFREY CARMICHAEL AND PETER W. STEBBING\*

In his comment on our 1983 paper on Fisher's paradox, Patrick Honohan argues that: 1) the use of first differences in our preferred equations leads us to seriously underestimate the potential errors-in-variables bias under Fisher's hypothesis we reported (fn. 9, p. 623); 2) the use of the *CPI* may make this potential bias even bigger; and 3) the implicit rate of return on holding money need not be independent of the expected rate of inflation.

The latter two points are quite trivial. With respect to the second point, all price series in Australia are highly correlated (contrary to Honohan's assertion)—this includes their rate of change and the change in their rate of change. Consistent with this observation, we tested several alternative price series and found the results to be invariant to the particular series chosen. We did not test alternative series for the United States. Given that all empirical tests (of which we are aware) of Fisher's hypothesis using U.S. data use the *CPI*, the onus would appear to be on Honohan to establish that the *CPI* is not a suitable index of prices, and that its use biases the results in a systematic way. His third point is equally irrelevant since the (approximate) independence of the implicit rate of return on money (our variable  $z$ ) and inflation is the hypothesis being tested. To assert that it may not be so, hardly advances our understanding of the issue at hand.

His first point, however, is more interesting. Our footnote 9 (p. 623) gives the general formula for the potential asymptotic errors-in-variables bias as  $b = -\sigma_\varepsilon^2 / (\sigma_{E\pi}^2 + \sigma_\varepsilon^2)$ . This formula is based on the assumption (our equation (6)) that observed inflation is the sum of expected inflation and a random error term:  $\pi_t = E\pi_t + \varepsilon_t$ .

Provided the process generating  $E\pi$  is independent of past forecasting errors, ( $\varepsilon_{t-i}$ ,  $i > 0$ ), the formula reported in footnote 9 is unaffected by first differencing the estimating equation or by correcting for serial correlation. If the process is not independent of  $\varepsilon_{t-i}$ , the calculation of the potential bias is affected. Since the calculations reported in footnote 9 use Douglas Pearce's ARIMA model for expected inflation, it is definitely incorrect.

We should emphasize at this point that it is not our estimates of the Fisher coefficient that are being questioned—it is our calculation of the potential bias in this coefficient that would exist if in fact Fisher were correct and we were wrong. To bring the issue into perspective we need to ask: first, how wrong might our calculation have been? And second, how important is the calculation to our conclusions?

The answer to the first is far from straightforward. Honohan suggests that using the general expression for the bias and Pearce's model for expected inflation gives a calculated bias closer to  $-0.85$  (our initial calculation was  $-0.12$ ). However, as he notes, this involves applying Pearce's coefficients to the log of prices rather than to the level. The need to do this arises because it is not possible to solve Pearce's actual model for a simple analytic expression for the bias. Applying Pearce's coefficients for the level of prices in a model for the rate of inflation involves a massive act of faith (indeed, we could not even go close to replicating Pearce's parameters when we tried to estimate an ARIMA model for the rate of inflation). Our hesitancy to embrace Honohan's calculations based on his arbitrary use of Pearce's coefficients reflects our belief in the critical importance of the model of expected inflation to the whole issue of measuring the potential errors-in-variables bias.

At the heart of the issue is the relative sizes of the variances of  $\varepsilon$  (the forecast error of the actual inflation rate) and  $E\pi$  (the time

\*International Department, Reserve Bank of Australia, Sydney 2001, Australia. The views expressed herein are our own, and are not necessarily shared by our employer.

path of expected inflation). If the process for  $E\pi$  depends *only* on past actual rates of inflation, the variance of  $E\pi$  will itself be a function of  $\epsilon$  only. For example, a simple  $AR(1)$  model,  $E\pi_t = \theta_0 + \theta_1\pi_{t-1}$ , gives  $\sigma_{E\pi}^2 = \theta_1^2\sigma_\epsilon^2/(1 - \theta_1^2)$ . In this simple model, the variance of expected inflation is infinite (and the potential bias very small) when  $\theta_1 = 1$  and zero (bias equal to minus one) when  $\theta_1 = 0$  (since  $\theta_1 = 0$  makes  $E\pi$  a constant).

It is a straightforward exercise to show that, with serial correlation in the estimating equation for the real interest rate, the size of the calculated potential errors-in-variables bias diminishes as other variables are added to the model for expected inflation. In the limit, expected inflation is independent of past prices and the expression in our footnote 6 (p. 633) is once again valid. All this emphasizes that one's estimate of the bias is critically dependant on the choice of model for expected inflation.

Finally, we turn to the importance of Honohan's point. So far we have emphasized the *potential* nature of the errors-in-variables bias. That is, it is only present if our null hypothesis of inverted Fisher is incorrect. In our equation 1.G (Table 1), we tested the alternative hypotheses using Pearce's expected inflation series directly. Since this equation does not contain a potential errors-in-variables problem, its support of the inverted Fisher hypothesis makes measurement of the potential bias irrelevant (or, at most, of second-order importance). The matter should rest there, but we are tempted to make one final point.

In our opinion, the errors-in-variables defense has been used as a crutch to explain why the data have consistently failed to support Fisher's hypothesis. From a purely technical perspective, those who believe in the Fisher effect for short-term financial interest rates can possibly find some solace in the errors-in-variables line of argument. Closer inspection of the data, however, should strain its credibility even to the most enthusiastic supporter. Our Figure 3 (p. 627), for example, tells a quite striking story. For Fisher to be correct, the true expected real after-tax rate of return would have to be a horizontal line through the middle of the graph, as would be the true expected rate of inflation. The difference between the true variables and the actual levels shown on the graph would need to be written off as erratic *ex post* movements, bearing no relationship to *ex ante* values. This might be convincing if those movements appeared to be erratic. In fact, what is striking about all three figures in our paper is the *systematic* nature of the movements. At least with respect to the data period in question, it is time for the crutch to be discarded.

## Predictable Behavior: Comment

By RICHARD BOOKSTABER AND JOSEPH LANGSAM\*

Ronald Heiner's article in this *Review* (1983), argues for a new approach to the realm of behavior under uncertainty. He proposes that an action will only be added to the repertoire of actions if certain criteria of reliability are satisfied for that action. He argues that given increased uncertainty, the repertoire of actions will be limited. With few actions from which to choose, the individual's behavior will be more predictable. He then suggests that this explains behavior in a surprisingly wide range of applications, ranging from the evolution of social institutions to the structure of DNA.

In Heiner's enthusiasm, he has not thoroughly developed the analysis and given the helpful perspective that would come from relating his ideas to the expected utility-maximization framework that is already established in economic theory.<sup>1</sup> In particular, in his attempt for maximum abstraction to permit the most broad generalizations, Heiner gives no example of how his model could be used in extending the conventional framework of behavior under uncertainty. We will try to fill this gap by rephrasing his nomenclature, to the extent that we can properly interpret them, into a more classical framework.

### I. Reformulating the Analysis in an Expected Utility Framework

We will use a simple two-state model with a repertoire consisting of a single action,  $r$ , and with a known payoff matrix, giving values for taking the action  $r$  for states  $S=0$  and  $S=1$  of  $U(r,0)$  and  $U(r,1)$ , respec-

tively. The action,  $a$ , under consideration has the property that  $U(a,0) > U(r,0)$ , and  $U(a,1) < U(r,1)$ . The uncertainty induced by the environment is given by  $p(S=0)=p$  and  $p(S=1)=(1-p)$ . Perceptual uncertainty is introduced into the model by not permitting the individual to observe the state, but only to observe a random variable  $X$  with a distribution that depends upon the state. We let  $X$  take on the values 0 and 1. The probability that  $X=x$  given that  $S=s$  is given by  $p(X=x|S=s)$  or by  $p(x|s)$  when there is no chance for confusion. It should be noted that the fact that  $X$  is observed and that the states space  $S$  is a random variable incorporates the concepts of perceptual and environmental uncertainty.

Let us see how Heiner's model differs from this conventional model. Heiner begins by considering the "right" and "wrong" times to use an action. The right and wrong times depend upon the repertoire, which in this case has a single action. Using his notation, the right conditions for action  $a$  occur with probability  $\pi(e)$ . For action  $a$ , the right conditions occur when the state  $S$  is 0; therefore,  $\pi(e)=p$ .<sup>2</sup> In Heiner's paper, the term "right time" refers to uncertainty arising from the environmental variable only. The variable  $\pi(e)$  then cannot depend upon the distributional relationship between  $X$  and  $S$ . For an action  $a$  to be added to the repertoire, there must be a value  $x$  of the random variable  $X$  where the action  $a$  is preferred to the action  $r$ . We will therefore restrict our attention to the situation where the random variable  $X=x$ . In Heiner's framework, the right conditions for action  $a$  (i.e., when  $S=0$ ) are correctly recognized with probabil-

\*Morgan Stanley, 1251 Avenue of the Americas, New York, NY 10020, and Case Western Reserve University, Department of Mathematics and Statistics, Cleveland, OH 44106, respectively.

<sup>1</sup>Indeed, in Section I, Heiner suggests his analysis does not fit into the standard optimization paradigm.

<sup>2</sup>Heiner states: "Depending on the likelihood of different situations produced by the environment, the probabilities of the right or wrong time to select the action are written as  $\pi(e)$  and  $1-\pi(e)$ , respectively" (p. 565).

ity  $r(U)$ .<sup>3</sup> In our framework,  $r(U)$  equals  $p(X=x|S=0)$ . Similarly, the conditional probability of selecting the action  $a$  when it is actually the "wrong time,"  $w(U)$ , in our model is given by  $p(X=x|S=1)$ . The gains  $g(e)$  from selecting the action  $a$  under the right conditions are simply  $U(a,0)-U(r,0)$ , while the losses  $l(e)$  from selecting  $a$  under the wrong conditions are  $U(a,1)-U(r,1)$ . Note that when  $X=x$ ,  $\pi(e)r(U)$  is equivalent to  $p(X=x|S=0)=p(X=x, S=0)$ . Similarly,  $w(U)(1-\pi(e))=p(X=x, S=1)$ .

When will the action  $a$  be added to the repertoire of possible actions?—clearly when there is a value of  $X$  such that  $a$  would be chosen. Rephrasing his reliability condition, this will occur when for some  $x$ ,

$$\begin{aligned} & [U(a,0)-U(r,0)]p(S=0, X=x) \\ & + [U(a,1)-U(r,1)]p(S=1, X=x) \geq 0. \end{aligned}$$

If we divide by  $p(X=x)$  and rearrange terms, we find that for some  $x$ , it must be the case that

$$\begin{aligned} & U(a,0)p(X=x|S=0) \\ & + U(a,1)p(X=x|S=1) \\ & \geq U(r,0)p(S=0|X=x) \\ & + U(r,1)p(S=1|X=x). \end{aligned}$$

That is, an action  $a$  will be added for this repertoire only if there is a set of information for which it has higher expected utility than the action that is already in the repertoire.<sup>4</sup>

<sup>3</sup>Heiner states: "The conditional probability for selecting the action when it is actually the right time is written  $r(U)$ , where the likelihood of so doing depends on the structure of uncertainty,  $U=u(p, e)$ " (p. 565).

<sup>4</sup>While Heiner's concepts of  $g(e)$  and  $l(e)$  are too amorphous to model in the more general case of an arbitrary repertoire, it seems reasonable to assume that his intent is for an action  $a$  to be considered only if there is some value of  $X$  such that the expected utility of  $a$  is greater than the supremum of the expected utility of all other actions in the repertoire. Footnote 18 states performance "...may involve some kind of average over actions and/or environmental conditions" (p. 566), which certainly would suggest expected utility. He

This reliability condition appears to be identical to the condition that will arise out of a simple two-state expected utility-maximization model: an action will not be considered if there does not exist a situation where that action has expected utility that is at least as great as the other available actions.

## II. Comments on Model Specification

Heiner's model, recast in these terms, seems to fit quite comfortably in the conventional framework of expected utility maximization. In many important respects, it gives results that appear to be identical to those of the expected utility-maximization model. However, his approach does lead to some difficulties.

First, his "right time/wrong time" analysis can lead to strange results when his two-action model is extended to include a third action. In particular, in his model it may never be the right time to do action  $a_0$  even when the expected utility of this action dominates that of the other two actions.

If, for example, the repertoire consists of the actions  $q$  and  $r$ , where  $U(q,0) > 0 > U(r,0)$  while  $U(q,1) < 0 < U(r,1)$ , then it would seem that it would never be the right time for any action  $a$ , where  $U(a,0) < U(q,0)$  and  $U(a,1) < U(r,1)$ . If the probabilities that  $S=0$  given  $X=0$  and that  $S=0$  given  $X=1$  are strictly between zero and one, it is easy to construct choices for  $U(a,0)$ ,  $U(q,0)$ ,  $U(r,0)$ ,  $U(a,1)$ ,  $U(q,1)$ , and  $U(r,1)$ , such that  $U(q,0) > U(a,0) > 0 > U(r,0)$ ,  $U(q,1) < 0 < U(a,1) < U(r,1)$ , and where any reasonable observer would agree that action  $a$  dominates the actions  $q$  and  $r$ . The example can easily be constructed where, for either choice of  $X$ , the expected utility from choosing actions  $q$  and  $r$  is very negative while the expected utility when choosing action  $a$  is positive.<sup>5</sup>

also states that " $g(e)$  and  $l(e)$  still represent the gain or loss in performance from correct or mistaken selections, respectively...."

<sup>5</sup>It is possible that Heiner intended for his argument to be used not in determining when an action should be

This problem in Heiner's analysis results from having  $\pi(e)$  depend only upon the environmental variable. While  $e$  is the only argument of  $\pi(\cdot)$  in Heiner's paper, it is clear that this is a misspecification of the correct functional form; his variable  $p$  must also be included in  $\pi(\cdot)$ . To see this, note that the structure of uncertainty is represented by  $U = u(p, e)$ , and the conditional probabilities  $r(U)$  and  $w(U)$  are therefore also functions of both  $p$  and  $e$ . The unconditional probability  $\pi(\cdot)$  must therefore also have both  $p$  and  $e$  as arguments to have a functional form consistent with  $u(\cdot)$ .

But if  $\pi(e, p)$  is used in the reliability condition in place of  $\pi(e)$ , this will lead to problems of its own for Heiner's later analysis. The right-hand term of the reliability condition will no longer be constant as  $p$  varies, violating an assumption he uses throughout the many examples of the paper.<sup>6</sup> Specification of a tolerance limit (see his p. 566, and Figure 1) now becomes problematic, and it no longer becomes clear that "greater uncertainty [resulting from changes in  $p$ ] will in general require a more inflexible structure of rules" (p. 574), since both sides of reliability ratio may change with a change in  $p$ .<sup>7</sup>

---

added to the set of actions, but when a decision rule should be added to a repertoire of existing decision rules. In our illustration, a decision rule would be a function from the range of  $X$  into some specified set  $A$  of what we have called actions. Since the right time in Heiner's analysis is dependent only upon the uncertainty introduced by environmental variables, this would force the probability of it being the right time for a decision rule to be independent of the distributional relationship between the domain of the decision rule and the state of nature. This of course must lead to the same apparent contradictions as our earlier interpretation of Heiner's intent.

<sup>6</sup>It should be noted, however, that Heiner's fnn. 18 and 53, as well as the discussion in subsection E (p. 575), suggest an interaction between  $e$  and  $p$  that is not present in the analytical framework of the paper itself.

<sup>7</sup>There is also the issue of just what is meant by greater uncertainty. Nowhere in the paper is there presented a dynamic framework to show how the repertoire will change as uncertainty changes. His analysis as presented is for given levels of uncertainty, and does not contain a dynamic structure.

The rationale for using  $p$  and  $e$  rather than just one (noisy) information variable, such as  $X$  in the above example, is unclear. Both  $p$  and  $e$  are attacking the same factor, that of noise in the information. Either the environment is becoming less clear, so  $e$  is increasing, or the ability of the individual to extract information is diminishing, so  $p$  is decreasing. Either the world is growing darker or the individual's vision is dimming. Both situations lead to exactly the same result for the model: there is more noise in the information variable. This situation is easily treated in the more conventional model where the individual cannot observe  $p(S=s)$  directly, but can only observe  $p(s|x)$ . Adding noise simply requires a reevaluation of actions, as  $X$  becomes more noisy, there may be some actions that decline in expected utility for those values of  $X$  where they might have been taken, and they will then be dropped from consideration in the repertoire.

### III. Does Increased Uncertainty Necessarily Lead to a More Restricted Set of Actions?

While Heiner's principal thesis is that uncertainty leads to a reduced set of possible actions, it is actually equally plausible that some uncertainty will *increase* the total number of actions in the repertoire. It may be that with uncertainty, the actions currently in the repertoire remain optimal in some cases while other actions now become better in other cases. To illustrate this point, consider a single two-state, three-action example. Let  $U(a_1, s_1) > U(a_0, s_1) > U(a_2, s_1)$ , and  $U(a_2, s_2) > U(a_0, s_2) > U(a_1, s_2)$ . Thus,  $a_0$  is an "insured" action that leads to moderate utility in both states. Suppose  $X$  can take on three values,  $x_0$ ,  $x_1$ , and  $x_2$ , and further, that  $p(s_1|x_0) = p(s_1|x_1) = .99$ , and  $p(s_2|x_2) = .99$ . Here there is little uncertainty, and it is easy to find values of  $U(\cdot)$  which preserve the above inequalities and which will lead to the individual selecting action  $a_1$  when  $X = x_0$  or  $X = x_1$ , and selecting  $a_2$  when  $X = x_2$ . Now suppose we introduce more uncertainty by letting  $X$  be a weaker signal of the true state. If  $p(s_1|x_1) = .99$ ,  $p(s_2|x_2) = .99$ , while  $p(s_1|x_0) = .5$ , it is clear

that the values of  $U(\cdot)$  may be such that  $a_0$  will now be selected when  $X = x_0$ .<sup>8</sup> Thus, more uncertainty will lead to a richer set of actions.

#### IV. Does A Restricted Set of Actions Imply More Predictable Behavior?

While Heiner's model can be recast, and perhaps even benefited, in the conventional framework, he may consider the key implications he draws from the model to be even more important than the model itself. As his title suggests, his thesis is "that uncertainty becomes the basic source of predictable behavior." This thesis does not seem to follow from the implications of his analysis, however. The conclusion that he appears to try to draw in his analysis is that uncertainty leads to a restriction of the size of the repertoire of actions. It is not at all clear that choosing from a smaller set of actions leads to behavior that is more predictable. We would view predictability as coming from observations coinciding with the model in question. A restricted set of actions will not be predictable if the model of behavior suggests a large set of actions should be used.

Heiner fails to give a definition of predictability, and the concept of predictability that is central to his conclusions does not appear within his analytical framework. It is therefore difficult to address his claims regarding predictability directly. But as a simple illustration of the problem of making the leap from restricted behavior to predictable behavior, imagine an economist who models an agent's behavior as a function of some information variable  $X$ , and finds the optimal decision rule is to choose an action  $a$ , such that  $a = x$ ,  $x = 1, \dots, 10$ . If the individual follows the more restrictive set of actions,

$a = 3$  for  $x = 1, \dots, 6$  and  $a = 7$  for  $x = 7, \dots, 10$ , will his behavior be more predictable?<sup>9</sup>

These comments notwithstanding, we do not intend to discard the notion that uncertainty may lead to more inflexible or rule-bound behavior. Rather, we are suggesting some difficulties with Heiner's particular approach. Indeed, in our forthcoming paper, we have shown that a particular type of uncertainty, uncertainty which is not captured by the individual's model or world view, may lead to coarse decision rules, decision rules which do not make fine adjustments to information, and which therefore appear to be rigid or rule bound. With this uncertainty, an observer viewing the individual's behavior and comparing that behavior with the behavior which would be predicted by the individual's model will find unaccountable invariance to information: while the model indicates a fine adjustment to changes in information, the agent will be unaccountably coarse in his response. We agree with Heiner that such unexplained rigidity is a major problem in economic theory. And, as the theory becomes more sophisticated, the gap between the fine-tuned response that is predicted and the coarse response observed becomes more troublesome.<sup>10</sup>

#### V. Conclusion

Heiner's claims are bold and wide-ranging. But his model does not appear to differ from the classical optimization model in the way that leads to the conclusions of restricted variability of behavior he wishes to draw. Furthermore, it remains unclear whether restricted variability of actions will lead to the

<sup>8</sup>Intuitively, what is happening is that as the performance of the repertoire drops, that drops the standard of performance the individual compares new actions to, and lowers the tolerance limit. The reliability is lowered enough so a new action can be introduced the repertoire.

<sup>9</sup>On a more concrete level, consider schizophrenic behavior. Although typically characterized by a very limited set of actions, and actions that remain unchanged for wide variations in information, this behavior is extremely difficult to predict; it appears almost random in its relationship to the information received.

<sup>10</sup>This problem with complexity is mentioned early in his fn. 4 (p. 561).

greater predictability of behavior he implies. The true nature of his contribution might be easier understood if his analysis is placed in a more conventional model. In this way, it will also be easier to actually apply his claims to the existing models, and verify the validity of the many examples he presents in his paper. Our attempt in this comment has been to provide some aid in this regard.

# Predictable Behavior: Comment

By ROGER W. GARRISON\*

In a recent paper in this *Review* (1983), Ronald Heiner identifies "uncertainty in distinguishing preferred from less-preferred behavior" (p. 561) as the *sine qua non* of predictable behavior. Examples drawn from diverse disciplines (physical chemistry, biology, economics, and others) are evidence of the scope and richness of this insight. Yet, when the most basic law of economics, the Law of Demand, is reformulated in terms of Heiner's uncertainty-based behavior, the analysis becomes suspect. It fails to allow for the theoretical possibility of a Giffen good. The purpose of this comment is to argue that Heiner claims, at the same time, too much and too little for his new analytical framework. He claims too much by insisting on an unqualified inverse relationship between price and quantity demanded; he claims too little by failing to show how the qualifications needed in his own analytical framework parallel and complement the usual qualifications of standard price theory. Reconciling Heiner's Law of Demand with the more conventionally conceived Law of Demand can serve to defend standard price theory and to increase our confidence in the remainder of Heiner's analysis.

## I. Allowance for the Special Case of the Giffen Good

The Giffen good, whose existence in theory is rarely denied but whose existence in reality is in serious doubt, constitutes an exception to the general Law of Demand: an increase in price is accompanied by an increase, rather than a decrease, in the quantity demanded. This paradoxical price-quantity relationship is conventionally explained in terms of the relative strengths of the sub-

stitution effect and the income effect associated with a given price change.<sup>1</sup> If the income effect is opposite in sign and greater in magnitude in comparison to the substitution effect, price and quantity demanded will move in the same direction, and the good is a Giffen good. Acceptance of the conventional construction of demand curves, which accounts for both substitution effects and income effects, is an implicit admission of the possibility of a Giffen good—however unlikely its occurrence in reality. (By contrast, Heiner claims to have formulated the Law of Demand "without any qualification for income effects..." p. 580.)

To qualify the Law of Demand with an allowance for the special case of the Giffen good is to recognize the general limitations of the *ceteris paribus* assumption. If, in deriving the demand curve for a particular good, the *ceteris paribus* assumption is invoked in the strictest sense (which fixes income as well as all other prices, quantities, and expenditures), the resulting demand curve is a rectangular hyperbola.<sup>2</sup> That is, strict fixity in all other markets, including the "market" for cash balances, would leave as a residual a fixed expenditure in the market whose demand curve is being derived. To avoid this trivial result, numerous changes throughout other markets, each of negligible magnitude, are allowed for under the assumption of *ceteris paribus*. This permits the derivation of a nontrivial, downward-sloping demand curve.

The Giffen good is the result of circumstances under which the *ceteris paribus* assumption, even in the less-than-strict sense, cannot hold. For the income effect to be large enough to more than nullify the substitution effect, the good in question not only must be an inferior good but also must con-

\*Assistant Professor of Economics, Auburn University, Auburn, AL 36849. I am grateful to Don Bellante and Don Boudreaux of Auburn University for helpful suggestions on an earlier draft.

<sup>1</sup>See, for example, George Stigler (1966, p. 65).

<sup>2</sup>This problem with the *ceteris paribus* assumption is pointed out by Milton Friedman (1976, pp. 22–23).

stitute a substantial portion of the buyers' budgets. Grain or potatoes in underdeveloped economies are the most likely kind of goods to fulfill such specifications (see Stigler, 1947). Under these circumstances it is logically impossible to impound all other nonnegligible price and quantity changes in the *ceteris paribus* assumption. Such changes can be so substantial as to constitute a substantial change in real income whose effect, in theory, may outweigh the substitution effect. Alternatively stated, the consumers of, say, potatoes are so impoverished by a rise in the price of potatoes that they must even further restrict their consumption to this inferior good. As will be seen, this alternative statement allows us to see how the limitations of the *ceteris paribus* assumption implicit in Heiner's framework makes equal allowance for the existence, at least in theory, of the Giffen good.

## II. *Ceteris Paribus* in Heiner's Framework

In the analytical framework offered by Heiner, uncertainty in distinguishing between preferred and less-preferred behavior manifests itself as a gap between the "competence" of an economic agent and the "difficulty" in selecting the most preferred behavior (see his p. 562). The competence-difficulty gap, or *C-D* gap as Heiner calls it, forms the backdrop for the behavior of economic agents. Gains to behavior modification are attenuated by the probability that the environmental conditions which would justify such modifications exist and are correctly perceived; losses are similarly attenuated. Under conditions of uncertainty economic agents modify their behavior only when the prospective attenuated gains outweigh the prospective attenuated losses. Heiner summarizes the implicit decision rule with an inequality that relates the perception probabilities, which he calls the "reliability ratio," to the actual occurrence probabilities appropriately multiplied by the gain and loss functions, which he calls the "tolerance limit" (p. 556). Only when the reliability ratio exceeds the tolerance limit will economic agents actually modify their behavior.

The application of this decision rule to an environment in which prices are changing is

straightforward. A change in the price of a particular good will change the gain and loss functions associated with buying that good. Given the *C-D* gap, a fall in price will reverse the inequality for some economic agents causing additional agents to become buyers and existing buyers to buy additional quantities of the good. (Heiner's reasoning is slightly different from but compatible with my own: "a higher price requires purchasing behavior to be more reliable, which can be achieved only by reducing the probability of purchase" p. 580.)

It is important to recognize that in Heiner's framework the size of the *C-D* gap is impounded in a *ceteris paribus* assumption. Because it is difficult to even imagine a circumstance in which the competence of the agent and the difficulty in deciphering the environment move in the same direction and by the same "amount" (such that the *C-D* gap remains constant), the *ceteris paribus* assumption should be taken to mean that both *C* and *D* remain unchanged. In typical circumstances this assumption is fully warranted. There is no reason to believe that a change in a particular price has any discernible effect on either the complexity of the economic environment or the agent's competence to deal with it. Heiner's analysis is on as solid ground as standard price theory.

But paralleling the standard theory of demand, the Giffen good is associated with an atypical circumstance in which Heiner's *ceteris paribus* assumption cannot be maintained. When impoverished consumers are faced with an increased price in the one staple that makes up a large portion of their budgets, their choice set is affected in a non-negligible way. In the framework of standard price theory, we would say that their real incomes have been substantially reduced; in Heiner's framework, we would say that the complexity of the environment, and hence the difficulty in deciphering it, has been reduced. There is no reason to believe that the agents' "competence" has changed, but because of the new relationship between their incomes and the higher price of the staple good, their newly preferred behavior may become starkly clear: they must further limit their consumption to the staple good. Thus, the *C-D* gap, which must remain constant if

Heiner's derivation of the Law of Demand is to yield unambiguous results, has actually been reduced in a nonnegligible way as a result of the price increase. Although this reduction of the *C-D* gap does not, by itself, imply that agents will necessarily buy more as a result of a price increase, it does allow us to reconcile Heiner's analysis with the theoretical possibility of a Giffen good.

### III. Conclusion

Heiner makes the claim that in the simplicity of his logic is a "clear, unambiguous implication of the Law of Demand, which we have never been able to derive with traditional optimizing methods" (p. 580). But allowing for the possibility of a Giffen good does not constitute a shortcoming of traditional methods; this theoretical possibility, rather, must be allowed for in the traditional theoretical framework and in any other theoretical framework, including Heiner's. I have

shown that by focusing on the *ceteris paribus* assumption and its limitations, the Giffen good can be accommodated in Heiner's theory in a way that parallels the accommodation made in standard price theory. In both theoretical frameworks we can be sure that the Law of Demand holds only to the extent that the underlying *ceteris paribus* assumptions can be maintained.

# Predictable Behavior: Reply

By RONALD A. HEINER\*

Richard Bookstaber and Joseph Langsam (1985), along with Roger Garrison (1985), have questioned certain parts of my paper (1983; hereafter called the "Origin" paper) wherein I suggested a new framework for explaining behavior. While my reply must inevitably focus on points of misunderstanding, nevertheless I would like to express appreciation for their comments. Moreover, errors on their part are partially due to the very brief development of formal theory in the paper.<sup>1</sup>

## I. Comparing Reliability Theory with the Conventional Framework

Bookstaber and Langsam begin by questioning whether reliability analysis extends the conventional decision theory framework. This issue is partially dealt with in my recent sequel to the Origin paper (1985c). I here focus on a key related topic not developed in that paper. To do so, think of the following conceptual scheme:  $A$  = the set of choosable actions, where individual actions may be randomized strategies over a set of more basic actions;  $B$  = the subset of  $A$  representing an agent's behavior;  $\gamma(Z)$  = the set of consequences resulting from actions  $Z \subset A$ , where individual consequences represent alternative probability distributions over a set of elementary events or outcomes;  $C^i(\gamma(Z))$  = the consequences chosen from  $\gamma(Z)$  according to a choice function  $C^i$ , where  $i$  refers to the type of choice function.  $C^i$  might be a standard expected utility function or a "nonexpected utility" function recently

developed by Machina, Chew, Fishburn, Loomes and Sugden, etc. (see Mark Machina, 1983).

Within this framework, the maximizing postulate is that agents act "as if" the consequences resulting from their behavior are selected from the set of choosable consequences  $\gamma(A)$  according to a choice function  $C^i$ ; that is,

$$(1) \quad \gamma(B) = C^i(\gamma(A)).$$

In other words, *theory about  $C^i$  is connected to observed behavior by postulating equality (1)*. But what happens if we discover behavior for which equality (1) fails to hold? This may already be the case for certain provisionally verified behavior patterns (such as *framing effects, probability ambiguity effects, preference reversals*, etc.; see Machina). How are we to deal with such possibilities? A typical response might be to introduce more subtle curvature assumptions or additional utility variables into a  $C^i$  function. Yet attempting to reestablish equality (1) in this way can do so only by steadily weakening the explanatory power of the theory. With this issue in mind, let us consider the *reliability condition* for an action  $a \in A$ ,

$$(2) \quad \frac{r_a}{w_a} > \frac{l_a}{g_a} \cdot \frac{1 - \pi_a}{\pi_a} = T_a,$$

where  $r_a = p(a|R_a)$ ,  $w_a = p(a|W_a)$ ,  $\pi_a = p(R_a)$ ,  $1 - \pi_a = p(W_a)$ ;  $R_a$  = the "right" conditions for which selecting action  $a$  will at least maintain or raise performance compared to selecting only other actions besides  $a$ ;  $W_a$  = the "wrong" conditions for which selecting action  $a$  will reduce performance compared to selecting only other actions besides  $a$ ;  $l_a$  = the "loss" in performance when action  $a$  is selected under the wrong conditions  $W_a$ ;  $g_a$  = the "gain" in performance when action  $a$  is selected under the right conditions  $R_a$ .

\*Member, 1984-85, The Institute for Advanced Study, Princeton NJ 08540; and Department of Economics, Brigham Young University.

<sup>1</sup>The Origin paper focused on broad conceptual issues and related applications, thereby shrinking mathematical details to a minimum. For further modeling and experimental analysis see my 1984, 1985a,b,c papers.

As discussed in the Origin paper, the ratio  $r_a/w_a$  measures agents' "reliability" in selecting action  $a$  (i.e., their ability to select action  $a$  under the right conditions  $R_a$  without mistakenly selecting it under the wrong conditions  $W_a$ ). The formula for  $T_a$  represents the minimum required reliability or "tolerance limit" that must be satisfied before agents can benefit from allowing themselves the option of choosing action  $a$  (i.e., from allowing themselves the flexibility to select action  $a$  along with other choosable actions).

Next consider how standard theory determines which actions to select. This is done by using an optimal decision rule,  $B^*: X \rightarrow A$ , that specifies how agents react to messages from a set of information  $X$  by choosing actions in their behavior repertoire  $A$ . Equality (1) implies  $B^*$  selects actions if and only if they maximize (according to a choice function  $C^i$ ) the "posterior" attainable performance contingent on received information. That is,  $B^*$  always selects an action  $a$  when messages are received for which it maximizes the posterior attainable performance contingent on receiving those messages (where such messages together represent the set  $R_a$  defined above); and conversely,  $B^*$  never selects action  $a$  when messages are received for which it does not maximize posterior attainable performance (where the latter messages represent the complement to  $R_a$  defined by  $W_a = X - R_a$ ). Thus,  $B^*$  or equality (1) implies  $r_a = 1$  and  $w_a = 0$  for all actions in  $A$ . Consequently, so long as equality (1) is assumed,  $r_a$  and  $w_a$  can only assume the values 1 and 0, respectively.

In contrast, reliability theory does *not* assume equality (1), but instead uses a choice function  $C^i$  to determine the size of the gain and loss variables ( $g_a$  and  $l_a$ ) of the tolerance limit  $T_a$  (see my 1984 paper for a precise discussion). Using a  $C^i$  function in this way implies no restriction on the  $r_a$  and  $w_a$  probabilities, thereby allowing one to investigate the larger set of possibilities defined by the inequality  $0 \leq w_a, r_a \leq 1$ . On the other hand, the above analysis implies equality (1) will in general be violated (except at the boundary of the preceding inequality). This conclusion can be formally stated by letting

$B^{Ci}$  denote the decision rule derived from a choice function  $C^i$  using the reliability condition. The following inequality can then arise,

$$(3) \quad \gamma(B^{Ci}) \neq C^i(\gamma(A)).$$

Now think of this in terms of the above mentioned experimental violations to equality (1). Inequality (3) means that the properties of choice functions like  $C^i$  do not necessarily carry over to the behavior  $B^{Ci}$  derived from them with the reliability condition (i.e.,  $C^i$  and  $B^{Ci}$  do *not* necessarily have the same properties). Consequently, *evidence that observed behavior violates equality (1) no longer contradicts using a  $C^i$  function to theoretically explain behavior.*<sup>2</sup> Instead, inequality (3) opens up the general possibility of modeling how and under what conditions the properties of  $B^{Ci}$  will deviate systematically from those satisfied by  $C^i$ . We can thereby retain the key analytical features of existing choice functions, yet use them to explain why observed behavior may fail to satisfy those same properties (see my 1984 paper).

The above discussion also applies to Bookstaber and Langsam's attempt to recast the reliability condition in terms of the conventional decision framework. They introduce so-called "perceptual uncertainty," but still in the traditional form represented by likelihood functions that give the probability of observing particular messages under different states of the environment. This leads them to argue that the  $p$  and  $e$  variables<sup>3</sup> introduced in the Origin paper are unnecessary for describing uncertainty. Standard theory suggests this view because (as dis-

<sup>2</sup>For example, observed violations of the Independence Axiom no longer contradict using an expected utility function to explain behavior.

<sup>3</sup>The  $p$  variables refer to agents' decision skills in reacting to information, and the  $e$  variables to the complexity-stability of their environment. Both sets of variables can be divided into subcategories. For example, the  $p$  variables include *perceptual skills* in observing and encoding potential information, *cognitive skills* in processing encoded information and deciphering how to respond to it, and *execution skills* in implementing behavior strategies suggested by the first two skills.

cussed above) it assumes agents optimally respond to information (i.e., standard theory models the perfect response to imperfect information).

However, no matter how rigorous and general such theory might appear, it only allows the  $r_a$  and  $w_a$  probabilities to be 1 and 0, respectively.<sup>4</sup> In contrast, the reliability condition enables one to investigate possibilities that extend well beyond the statistical properties of how information imperfectly reveals the environment. Consequently, giving up equality (1) or  $B^*$  does *not* mean we are left without a theory. Rather *it simply means we investigate the consequences of  $r_a$  and  $w_a$  away from the boundary values of 1 and 0*. Finally, note that we still have at our disposal major portions of existing statistical and utility theory to formally analyze how these probabilities change under different conditions. We can thereby model behavior without the maximizing postulate, yet still use the major analytical tools traditionally associated with it.<sup>5</sup>

## II. Uncertainty and Predictable Behavior

Let us next turn to another issue in Bookstaber and Langsam's comment about the appropriate meaning of predictable behavior. They suggest a predictability criterion which asks whether a behavior pattern is predicted correctly by an agent's theoretic-

cal model of what behavior (so that behavior mistakenly predicted by the model becomes *unpredictable* to the agent). By this criterion, someone with a faulty theory of planetary movement would regard their behavior as "unpredictable" even though their rigidly patterned celestial movements might be the very motivation for constructing the theory in the first place. As such, Bookstaber and Langsam's criterion confuses the difficulty of an observer detecting recurrent pattern in behavior with the difficulty of successfully explaining such pattern.

I do not wish to argue about what is the "correct" definition of predictability, except to say that I have the former idea (detecting recurrent pattern) in mind. This can be formalized by entropy measures used in statistical mechanics and information-cybernetics' theory. Let  $h_a$  denote the probability of selecting action  $a$ ,  $h_a = p(a)$ . Then agents' *behavioral entropy* equals the following sum over actions in  $A$ ,  $E^B = -\sum h_a \log h_a$ .  $E^B$  increases as the number of actions agents might select increases, but no single action is frequently chosen (reaching a maximum when all actions are equally likely to be selected; see Claude Shannon and Warren Weaver, 1963). Entropy measures have been extensively analyzed in several fields, thus enabling a number of key theorems and relationships to be readily accessed for new applications (for some examples, see my 1985c paper).

I now turn to the main thesis of the Origin paper whose validity is questioned by Bookstaber and Langsam; namely, the relationship between uncertainty and predictable behavior. To do so, let  $\rho$  denote the set of all  $r_a/w_a$  ratios for choosable actions in  $A$ . The set  $\rho$  describes an agent's reliability in reacting to information about when to select specific actions. The special case where agents are perfectly reliable is denoted  $\rho^\infty$ , meaning the  $r_a/w_a$  ratios are all infinite.  $\rho$  is said to be *bounded* if the reliability ratios of each action do not exceed a finite upper limit. In the case of  $\rho^\infty$ , agents still face "risk" due to imperfect information, but no additional uncertainty is involved. The term "uncertainty" thus refers to the case where agents' reliability  $\rho$  is bounded. In addition, let  $\rho^1$  denote

<sup>4</sup>One can also use likelihood functions of standard theory to measure the reliability of information used by agents (where the probabilities involved are unrestricted between 0 and 1). However, these probabilities do *not* measure agents' reliability in responding to information. See my 1985c paper for a two-stage reliability formula that combines both sources of uncertainty (from imperfect information and imperfect response to information).

<sup>5</sup>This also applies to using maximizing tools. For example, first-order conditions can be developed by differentiating  $r_a$  and  $w_a$ . However, doing so is redundant unless these probabilities can deviate from 1 and 0, which is possible only if decision rules besides  $B^*$  are used (otherwise the derivatives of  $r_a$  and  $w_a$  would always equal zero). In conceptual terms this means we can use  $r_a$  and  $w_a$  to derive optimizing conditions that are *conditional* on agents' true decision skills instead of having to abstract from them by assuming equality (1) or  $B^*$  (see my 1985a paper).

the other extreme case where agents are completely unable to distinguish right from wrong information for selecting different actions (so that they are equally likely to select actions under either  $W_a$  or  $R_a$ ). Thus,  $\rho^1$  means  $r_a/w_a=1$  for all  $a$ . The reliability sets describe a range of uncertainty possibilities, beginning with  $\rho^1$  at one extreme, and proceeding through intermediate cases where  $\rho$  is still bounded, finally limiting on  $\rho^\infty$  where only imperfect information remains.

Next consider the example constructed in Section III of Bookstaber and Langsam's comment. They introduce more risk (i.e., noisier information) in order to selectively reduce the performance achievable with two out of three possible actions, thereby expanding an agent's repertoire to include a third action. This is an instance of a more general possibility whereby two or more actions initially outperform another action for all potentially received information, but eventually fail to do so as the achievable performance from them drops sufficiently (due to worse information as in Bookstaber and Langsam's example, or because agents become less reliable at using information). Conversely, an action may initially dominate two or more other actions but fail to do so as agents have better information about when to select other actions or more reliably respond to such information.

It is possible that the transition from selecting a given action to selecting other ones may temporarily have agents benefiting from selecting all of them (i.e., their repertoire may initially expand to include a given action plus other ones before dropping out the former action; and vice versa). Consequently, such a transition may not always be monotonic. Note, however, the full transition necessarily involves a net shift between a given action and at least two other ones. This is because at least two other actions are needed to outperform a given action. If only one other action was involved, it would have to outperform the given action for all potentially received messages (thereby preventing that action from being selected in the first place).

The above considerations suggest that a pattern may emerge if we do not restrict

ourselves to special examples involving only small numbers of actions. Such is in fact the case. Two results can be proved with general assumptions about the relative numbers of different kinds of actions and how the performance resulting from them varies under different conditions.<sup>6</sup>

These results are briefly described as follows. Given agents' reliability in responding to information specified by  $\rho$ , individual actions are added to their behavioral repertoire only if the reliability condition for selecting them is satisfied. Conversely, actions can be deleted if at some point the reliability condition fails to hold. Additions and deletions continue until no excluded action satisfies the reliability condition and no included action violates it.<sup>7</sup> Finally, let  $E^B(\rho)$  denote the behavioral entropy resulting from this process for any given  $\rho$ . One can then prove two basic results:

A. Agents' behavioral entropy  $E^B(\rho)$  will drop from an initially positive level as  $\rho$  changes sufficiently toward  $\rho^1$ ; and conversely,  $E^B(\rho)$  will increase as  $\rho$  shifts sufficiently toward  $\rho^\infty$ .

B.  $E^B(\rho)$  is bounded if and only if  $\rho$  is bounded.

The results A and B describe a general pattern where sufficient changes in the reliability of responding to information will strictly raise or lower behavioral entropy away from its initial level. However, the shift between successively higher or lower entro-

<sup>6</sup>In particular, there must be enough variety of performance from different actions for there always to be a potential benefit from selecting more actions; there can only be a finite number of actions able to outperform another set of actions more often than a given positive fraction of the time, and the gains and losses from selecting individual actions cannot become arbitrarily large or small relative to each other.

<sup>7</sup>The order of adding or deleting particular actions need not be specified, or they can occur statistically (for example, the probability of adding or removing individual actions may depend on how much performance would change by doing so compared to that caused by adding or removing other actions). The theorem holds so long as the process cannot indefinitely add actions for which the resulting gain in performance is arbitrarily small compared to that of other actions which also satisfy the reliability condition but have not yet been included.

pies may not always be monotonic. Nevertheless, result B makes clear that is the boundedness of  $\rho$  (i.e., the presence of uncertainty) which limits agents' behavioral entropy. Thus, while the effects of uncertainty may not be continually monotonic, we can still regard uncertainty as the source of predictable behavior in the following sense:<sup>8</sup> without uncertainty affecting agents' decisions, recurrent pattern in their behavior (noticeable to an observer because  $E^B(\rho)$  is bounded) would not arise in the first place.<sup>9</sup>

Let us now briefly turn to two remaining points of lesser importance.

1) Bookstaber and Langsam argue that the reliability model is misspecified by not putting an agent's perceptual variables  $\mathbf{p}$  into the  $I_a, g_a, \pi_a$  components of the tolerance limit  $T_a$  (as first stated on p. 566 of the Origin paper). The possibility of  $\mathbf{p}$  variables affecting these components is, however, suggested later in the paper (see fnn. 18, 15; and p. 575). Noting the omission of  $\mathbf{p}$  from the initial specification is nevertheless a valid point. However, Bookstaber and Langsam also claim this omission produces substantive problems. This is mistaken. Explicitly putting  $\mathbf{p}$  into  $T_a$  simply makes clear that it may potentially affect both sides of the reliability

condition, as already the case for the  $\mathbf{e}$  variables.<sup>10</sup> (Note that this does not mean both sides of the reliability condition are noticeably or equally affected by every  $\mathbf{p}$  or  $\mathbf{e}$  variable.)

2) In Bookstaber and Langsam's Section II, an example with three actions is constructed; where there always exist states in which a first action is outperformed by one of the remaining two actions. This leads them to mistakenly interpret right and wrong circumstances ( $R_a$  and  $W_a$ ) to imply that only the remaining two actions can be chosen. However,  $R_a$  and  $W_a$  are *not* defined relative to the maximum potentially achievable performance from selecting other actions, but instead relative to that achievable given imperfect information and the reliability of responding to that information. Consequently, Bookstaber and Langsam's conclusion (that the reliability condition would not allow the first action to be chosen) is mistaken.

### III. The Law of Demand

Standard choice theory shows that an optimizing consumer can benefit from buying more when prices rise (called a Giffen response, or  $G$ -response) instead of always buying less (the latter response called the "Law of Demand," or  $L$ -response). However, the possibility of a  $G$ -response is usually ignored for practical purposes, largely because no credible evidence of Giffen behavior has even been documented (the Irish potato case notwithstanding; see Gerald Dwyer and Cotton Lindsay, 1984). Moreover, standard theory also suggests  $G$ -responses are unlikely since they can theoretically occur only for inferior goods that absorb more than a small fraction of consumers' total incomes. Nevertheless, a rea-

<sup>8</sup>Results A and B imply nonmonotonic effects of changing uncertainty are local deviations from a larger pattern that must nevertheless still hold. Consequently, instances of nonmonotonic effects like Bookstaber and Langsam's example do not contradict the basic relationship between uncertainty and predictable behavior. However, their example is still helpful in suggesting the need to qualify the intuitive language of the Origin paper. Accordingly, A and B specify the qualification while still affirming the paper's main thesis.

<sup>9</sup>The Origin paper also described the effects of uncertainty (see pp. 567–68) in terms of "behavioral rules" that restrict decision flexibility away from actions appropriate only for rare situations; or conversely, toward actions adapted to recurrent or "typical" conditions. An ambiguity may arise about the dual meaning of flexibility. Actions adapted to typical conditions can be described as "flexible" in handling a wide range of conditions (except unusual events that infrequently arise). In contrast, actions adapted only to infrequent conditions might be called "situation-specific" actions. Thus, behavioral inflexibility (*away* from situation-specific actions) also means agents flexibly adjust to (*only* the recurrent features of) their environment. The above was motivated by helpful discussions with Richard Langlois.

<sup>10</sup>As already mentioned above in Section I, Bookstaber and Langsam try to show that "noise in the information variable" can simulate the effects of both the  $\mathbf{p}$  and  $\mathbf{e}$  variables. However, if noisy information could really simulate  $\mathbf{e}$  (and  $\mathbf{e}$  can affect both sides of  $r_a/w_a > T_a$ ) then the components of  $T_a$  must thereby also depend on noisy information. This conclusion contradicts the opposite claim in Section I of their paper (that  $\pi_a$  cannot be affected by noisy information).

sonable interpretation of the theory would have to allow  $G$ -responses to be optimal at least some small fraction of the time (say, on the order of 3–5 percent of agents' reactions to different price changes over time).

Standard theory assumes agents are perfectly reliable at detecting when  $G$ -responses are more preferred than  $L$ -responses (corresponding to  $\rho^\infty$  as defined in Section II). Suppose, however, agents' decision skills are not sufficient to behave in this fashion. In particular, suppose agents are involved in an ongoing sequence of reactions to future price changes. A large number of interdependent factors affect the circumstances of individual price changes. For example, different commodities may be involved; spendable income or longer-term wealth may be different from one case to the next; the relative prices of other goods may be different; various psychological factors affecting their tastes may have changed, or ongoing experience with new consumption patterns may have altered previous tastes; the relative amounts spent on particular commodities may be different, including the one whose price changed; etc.

Note the last possibility. The fraction of income spent on particular goods may vary from case to case. Such variation is thus part of a large number of factors whose variation jointly contribute to the overall complexity of deciding how to respond to changing prices over time. Consequently, the difficulty of the decision problem is *not* defined assuming any given proportion of income spent on particular goods, *but instead already incorporates potential changes in this proportion as one of its many determining factors.*

Now compare this with Garrison's analysis. He assumes the fraction of income spent is like an exogenous parameter altering the difficulty of the decision problem from one case to the next, thereby violating implicit *ceteris paribus* assumptions of the Reliability Condition. This mistaken impression comes from viewing each price response in isolation (thus, permitting all sorts of changes in particular factors to possibly violate *ceteris paribus* assumptions). Once these isolated reactions are seen as part of a larger ongoing decision problem, the difficulty of such a dynamic problem must incorporate all

potential variations of decision factors that might appear in each specific instance.

This is the case even if a larger fraction of income spent increases the chance that  $G$ -responses are more preferred than  $L$ -responses (as possible for inferior goods). Such a criterion is not sufficient, but at best only necessary for  $G$ -responses to be more preferred. As already indicated, many other factors also affect when this is actually the case. Agents thus still face a nontrivial decision problem even for a subsequence of price reactions involving only goods that occupy sizable proportions of their future incomes.

I conclude with the following question: how can standard theory imply  $G$ -responses are optimal for some positive fraction of agents' ongoing price reactions, yet no stable frequency of Giffen behavior has been empirically discovered? Recall that  $h_G = p(G)$  is the chance of selecting a  $G$ -response, and  $\pi_G = p(R_G)$  is the chance of right conditions for  $G$ -responses (i.e., when they are actually more preferred than  $L$ -responses).

Standard theory implies agents select  $G$ -responses exactly as often as they are more preferred than  $L$ -responses, so that  $h_G/\pi_G = 1$  regardless of the size of  $\pi_G$ . On the other hand, when  $\rho$  is bounded, it can be shown for any action  $a$  that  $h_a/\pi_a \rightarrow 0$  as  $\pi_a \rightarrow 0$ . That is, the chance  $h_a$  of selecting an action must get arbitrarily small compared to the chance  $\pi_a$  of appropriate circumstances for selecting it as the latter probability gets smaller and smaller. Applying this to  $G$ -responses, we can easily have  $h_G$  vanishingly small compared to  $\pi_G$  just in the case where standard theory implies  $\pi_G$  is small but still positive. The latter result can be intuitively summarized as follows: the Law of Demand is a "behavioral rule" that would not have arisen if agents had the decision skills assumed in conventional choice theory (i.e., the extremely high predictability of the law owes its existence to uncertainty not present within this framework).

## Auditors' Report

February 22, 1985

Executive Committee  
The American Economic Association

We have examined the balance sheets of The American Economic Association as of December 31, 1984 and 1983, and the related statements of revenues and expenses, changes in general fund and restricted fund balances and changes in financial position for the years then ended. Our examinations were made in accordance with generally accepted auditing standards and, accordingly, included such tests of the accounting records and such other auditing procedures as we considered necessary in the circumstances.

In our opinion, the financial statements referred to above present fairly the financial position of The American Economic Association as of December 31, 1984 and 1983, its revenues and expenses and the changes in its financial position for the years then ended, in conformity with generally accepted accounting principles applied on a consistent basis.

Touche Ross and Co.  
Certified Public Accountants  
Nashville, Tennessee

### Notes to Financial Statements

#### A. Summary of Significant Accounting Policies

*Investments* are accounted for on a market value basis. According to the method the Association uses to value investments, the change in market value of corporate stocks, government obligations, bonds and commercial paper during the year, after adjusting for an inflation factor (3.7% in 1984 and 4.2% in 1983), is recognized in income over a three-year period for corporate stocks and reflected in current income for government obligations, bonds and commercial paper.

*The Accrual for directory* results because every three to five years the Association publishes a directory which lists, among other things, the names and addresses of its membership. This directory was most recently published in 1981 and distributed at no cost to the membership. In order to properly match the publishing cost of this directory with revenue from membership dues, the Association provided \$65,000 in 1984 and \$60,000 in 1983 for estimated publishing costs which will reduce actual directory expenses in the year of publication.

*Deferred revenue* represents income from membership dues for and subscriptions to the various periodicals of the Association which are deferred when received. These amounts are then recognized as income following the distribution of the specified publications to the members and subscribers of the Association. Income from life membership dues is recognized over the estimated average life of these members.

*The American Economic Association* files its federal income tax return as an educational organization, substantially exempt from income tax under Section 501(c) (3) of the Internal Revenue Code. As required by Section 511(a) of this Code, the Association provides for federal income taxes on certain revenues which are not substantially related to its tax exempt purpose. This "unrelated business income" includes income from advertising and the sale of mailing lists. The Association has been determined to be an organization which is not a private foundation.

**B. Investments and Investment Income**

Investments consist of:

	December 31, 1984		December 31, 1983	
	Cost	Market	Cost	Market
Government obligations, bonds and commercial paper	\$ 923,345	\$ 983,784	\$ 847,212	\$ 908,212
Corporate stocks and mutual funds	1,696,178	2,181,404	1,649,062	2,319,275
	<u>\$2,619,523</u>	<u>\$3,165,188</u>	<u>\$2,496,274</u>	<u>\$3,227,487</u>

Investment gains recognized consist of:

	Year Ended December 31	
	1984	1983
Government obligations, bonds, and commercial paper:		
Interest	\$176,304	\$151,144
Increase (decrease) in market value recognized	(28,084)	(76,584)
	<u>148,220</u>	<u>74,560</u>
Corporate stocks and mutual funds:		
Cash dividends	87,992	71,675
Increase in market value recognized (Note C)	48,345	19,012
	<u>136,337</u>	<u>90,687</u>
Investment gains, net	<u>\$284,557</u>	<u>\$165,247</u>

**C. Unrecognized Change in Market Value of Investments**

As described more fully in Note A, the Association recognizes in income over a three-year period changes in the market value of its corporate stocks. The following summarizes the years in which market value changes in stocks occurred that affected 1984 and 1983 revenues, and the amount of these market value increases (decreases) that will be recognized in income in future periods.

Year of Market Value Change	Recognized in Income in		To be Recognized in		Unrecognized Change	
	1984	1983	1985	1986	1984	1983
1981	\$ -	(\$139,131)	\$ -	\$ -	\$ -	\$ -
1982	88,397	88,396	-	-	-	88,397
1983	69,747	69,747	71,600	-	71,600	141,347
1984	(109,799)	-	(109,799)	(109,798)	(219,597)	-
	<u>\$ 48,345</u>	<u>\$ 19,012</u>	<u>(\$ 38,199)</u>	<u>(\$109,798)</u>	<u>(\$147,997)</u>	<u>\$229,744</u>

The Association's revenues in excess of expenses would have been (\$130,968) in 1984 and \$437,440 in 1983 if changes in the market value of corporate stocks, after adjustment for inflation, had been recognized only, but entirely, in the year in which they occurred.

The Association's investment gains would have been \$121,978 in 1984 and \$128,168 in 1983 if 4% of the market value of the portfolio had been considered investment income (without regard to dividends, interest, capital gains and inflation). Under this method, the Association's revenues in excess of expenses would have been \$84,195 in 1984 and \$208,279 in 1983.

**D. Retirement Annuity Plan**

Employees of the Association are eligible for participation in a contributory retirement annuity plan. Payments by the Association and participating employees are based on the employee's compensation. Benefit payments are based on the amounts accumulated from such contributions. The total pension expense was approximately \$27,000 and \$23,000 for 1984 and 1983, respectively.

**E. Ratio of Net Worth to Expenses**

The ratio of net worth at December 31, 1984 to 1985 budgeted expenses is 1.43 and the ratio of net worth at December 31, 1983 to actual 1984 expenses is 1.58.

**EXHIBIT 1—THE AMERICAN ECONOMIC ASSOCIATION STATEMENTS OF OTHER  
GENERAL AND ADMINISTRATIVE EXPENSES FOR THE YEARS ENDED  
DECEMBER 31, 1984 AND 1983**

	1984	1983
Dues and subscriptions	\$ 49,600	\$ 39,925
Mailing list file maintenance	23,617	24,385
Postage	16,478	15,788
Periodic mailing expenses	14,189	14,118
Accounting and legal	12,140	12,750
Investment counsel and custodian fees	11,960	11,267
Office supplies	11,988	10,582
Insurance and miscellaneous	4,088	9,006
President and president-elect expenses	5,648	5,315
Telephone	4,626	5,033
Depreciation (straight-line method)	3,780	3,677
Currency exchange charges	1,548	2,160
Uncollectible receivables	1,002	1,658
Travel and entertainment	1,533	737
	<u>\$162,197</u>	<u>\$156,401</u>

## NOTES

### *1986 Nominating Committee of AEA*

In accordance with Section IV, paragraph 2, of the bylaws of the American Economic Association as amended in 1972, President Elect Alice M. Rivlin has appointed a Nominating Committee for 1986 consisting of W. Arthur Lewis, Chair; William J. Beeman, William J. Boyes, Padma Desai, Thomas J. Finn, A. Nicholas Filippello, and Marjorie Honig.

Attention of members is called to the part of the bylaw reading, "In addition to appointees chosen by the President-Elect, the Committee shall include any other member of the Association nominated by petition including signatures and addresses of not less than 2 percent of the members of the Association delivered to the Secretary before December 1. No member of the Association may validly petition for more than one nominee for the Committee. The names of the Committee shall be announced to the membership immediately following its appointment and the membership invited to suggest nominees for the various officers to the Committee."

### *Nominations for AEA Officers: 1986*

The Electoral College on March 22 chose Gary S. Becker as nominee for President Elect of the American Economic Association in the balloting to be held in the autumn of 1985. Other nominees (chosen by the 1985 Nominating Committee) are: Vice President (two to be elected), Richard N. Cooper, Peter A. Diamond, Mancur Olson, and Thomas C. Schelling; for members of the Executive Committee (two to be elected), Donald F. Gordon, Sherwin Rosen, Thomas J. Sargent, and T. N. Srinivasan.

Under a change in the bylaws as described in the *American Economic Review Proceedings*, May 1971, page 472, additional candidates may be nominated by petition, delivered to the Secretary by August 1, including signatures and addresses of not less than 6 percent of the membership of the Association for the office of President-Elect, and not less than 4 percent for each of the other offices. For the purpose of circulating petitions, address labels will be made available by the Secretary at cost.

Donation available: Full years of the *American Economic Review* and the *Journal of Economic Literature* (1969-74). Contact Dr. Sophie Korczyk, 706 Little Street, Alexandria, VA 22301.

The eighth annual Middlebury College Conference on Economic Issues, "The Psychological Foundations of Economic Behavior," will be held October 25-26, 1985. For further information, contact Paul J. Albanese, Pro-

fessor of Economics, Middlebury College, Middlebury, VT 05753 (telephone 802+388-3711, Ext. 5322).

The National Institute on Aging invites grant applications for research and research training that focus on increases in longevity at the later ages, and the future explosive growth of that segment of the population. Application deadlines are March 1, July 1, and November 1. Contact Ms. Mildred D. Mader, National Institute on Aging, Bldg 31C, Rm 4C32, 9000 Rockville Pike, Bethesda, MD 20205.

The University of Venice will host a conference on Advances in the Analysis of Economic Dynamic Systems in January 1986. The focus will be on applications to economics of recent developments in the theory of nonlinear dynamic systems, to include nonlinear oscillations, bifurcation theory, catastrophe theory, synergetics, and irregular oscillations, or chaotic dynamics. Emphasis will be on use of deterministic models to describe certain irregularities of real economies that have so far been explained by means of stochastic models. Prospective contributors should submit full texts of approximately 15 typewritten pages by September 1985. No expenses will be paid; however, there will be prizes of one million lira each for the two best papers. Contact the Conference Secretary: Marji Lines, Dipartimento di Scienze Economiche, Università di Venezia, Dorsoduro 3246, Venezia 30123.

The Inter-University Consortium for Political and Social Research will hold its twenty-third Summer Program in Quantitative Methods of Social Research in Ann Arbor, July 1-August 23, 1985. The Program is divided into two 4-week sessions: July 1-26 and July 29-August 23. Individuals can attend either or both, or can participate in workshops lasting one week or less. For full information and the complete list of Course Offerings/Workshops, contact ICPSR official representatives at member colleges and universities, or the Director, Henry Heitowit, Educational Resources, ICPSR Summer Program, P.O. Box 1248, Ann Arbor, MI 48106 (telephone 313+746-8392).

Harvard Law School offers fellowships to college and university teachers in the social sciences and humanities to enable them to study fundamental techniques, concepts, and aims of law, so that, in their teaching and research, they will be better able to use legal materials

and legal insights which are relevant to their own disciplines. Further information may be obtained from the Chairman, Committee on Liberal Arts Fellowships in Law, Harvard Law School, Cambridge, MA 02138.

---

*Call for Papers:* The annual meeting of the Association of Environmental and Resource Economists (AERE) will be held jointly with the AEA in New York City, December 28–30, 1985. Those interested in having papers considered should send two copies of a one-page abstract to the President of AERE, Professor V. Kerry Smith, Department of Economics, Box 52 B, Vanderbilt University, Nashville, TN 37235.

---

*Call for Papers:* The AEA Committee on the Status of Women in the Economic Professions (CSWEP) will sponsor two sessions at the 1985 Southern Economic Association meetings, November 24–26, 1985, in Dallas at the Hyatt Regency Hotel. Those wishing to present theoretical or empirical papers for either session: "Comparable Worth: Applied Microeconomic Theory," or "Gender Effects of Taxes, Pensions, and Fringe Benefits," should contact Professor Marie Lobue, Department of Economics and Finance, University of New Orleans, New Orleans, LA 70148 (telephone 504 + 286-6485).

---

*Call for Papers:* UNEP (United Nations Environment Programme), the Autonomous University of Nuevo Leon of Monterrey, Mexico and the University of Cincinnati are organizing an international Conference on the Economics of Environmental Protection in Mexico to be held in Monterrey, October 14–18, 1986. Papers on the economic aspects of environmental protection in developing countries in general and in Mexico in particular are invited. Submit a one-page abstract as soon as possible. Authors from Mexico and Latin America should contact Lic. Manuel Silos M., Director, Facultad de Economía, Universidad Autónoma de Nuevo Leon, Apartado Postal 288, Monterrey, N.L. 64000, Mexico; all others contact Professor Haynes C. Goddard, Department of Economics (371), University of Cincinnati, Cincinnati, Ohio 45213.

---

*Call for Papers:* The Fourth International Congress of the North American Economics and Finance Association will be held July 23–26, 1986, at the Université de Montréal. Economic and financial topics relevant to Canada, Mexico, the Caribbean, and the United States will be covered and will be held in English, Spanish, and French. Deadline for submission of papers is January 1, 1986. To present papers, be a discussant, or chair a session, contact M. C. Thiron, Chairman of the Program Committee, c/o G. Gaudichon, CRDE-Department of Economics, Université de Montréal, C.P. 6128,

Succ. "A", Montréal, Quebec H3C 3J7 (telephone R. Tremblay: 514 + 343-6549; or 514 + 343-6657).

---

The Council for International Exchange of Scholars (CIES) announces the 1986–87 competition for Fulbright Scholar Awards in research and lecturing abroad. Benefits include round-trip travel for the grantee and, for full academic year awards, one dependent; living costs allowance; tuition as well as book and baggage allowances. Grants are for 3–12 months in over 100 countries. Applicants must be U.S. citizens, hold the Ph.D. or comparable professional qualifications, and have university or college teaching experience. Deadlines are June 15, 1985 for Australasia, India, Latin American and the Caribbean; September 15, 1985 for Africa, Asia, Europe, and the Middle East; November 1, 1985 for Junior Lectureships to France, Germany, Italy, and Spain; December 1, 1985 for Administrators' Awards in Germany, Japan, and the United Kingdom; December 31, 1985 for NATO Research Fellowships; and February 1, 1986 for Seminar in German Civilization Awards, Spain Research Fellowships, and France and Germany Travel-Only Awards. For more information and applications, contact CIES, Eleven Dupont Circle, NW., Washington, D.C. 20036-1257 (telephone 202 + 939-5401).

---

The Indo-U.S. Subcommittee on Education and Culture is offering twelve long-term (6–10 months) and nine short-term (2–3 months) awards for 1986–87 research in India. Applicants must be U.S. citizens at the postdoctoral or equivalent professional level. Fellowship terms include \$1,500 per month, of which \$350 per month is payable in dollars and the balance in rupees; an allowance for books and study/travel in India; and international travel for the grantee. In addition, long-term Fellows receive international travel for dependents; a dependent allowance of \$100–\$250 per month in rupees; and a supplementary research allowance up to 34,000 rupees. The application deadline is June 15, 1985. For application forms and further information contact Council for International Exchange of Scholars (CIES), Attn: Indo-American Fellowship Program, Eleven Dupont Circle, Suite 300, Washington, D.C. 20036-1257 (telephone 202 + 939-5472).

---

The fourth annual International Conference on Women and Organizations will be held in San Diego, CA, August 8–9, 1985. The theme is "Promoting Career Progress for Women: Effective Programs for Individuals and Organizations." Practicing managers, consultants, and academics are invited to attend. For further information, contact Jean Ramsey, Department of Management, Western Michigan University, Kalamazoo, MI 49008 (telephone 616 + 383-1357).

*Call for Papers:* The thirteenth annual meeting of the Midsouth Academy of Economics and Finance will be held February 13–15, 1986, in Memphis Tennessee. Paper proposals should be submitted by October 15, 1985. Those interested in chairing, discussing, or organizing special sessions should also contact David E. R. Gay, President-Elect, Midsouth Academy of Economics and Finance, Department of Economics, BA402, University of Arkansas, AR 72701.

The Society for Risk Analysis will hold its annual meeting on the theme, "Enhancing Risk Management," to be held in Washington, D.C., October 7–9, 1985. For further information, contact Janice Longstreth, ICF, 1850 K Street, N.W., Washington, D.C. 20031 (telephone 202+862-7915).

Piero Sraffa has named Pierangelo Garegnani literary executor in his will, leaving him the rights on all his writings. Garegnani has initiated work for an edition of Sraffa's writings to include correspondence. Any material (photocopies, information, personal recollections) would be appreciated. Contact Professor Pierangelo Garegnani, Department of Public Economics, Faculty of Economics, University of Rome, Via del Castro Laurenziano 9, 00161 Rome, Italy.

Economists who are strongly oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings held outside the United States, Mexico, and Canada that are concerned with the humanistic aspects of their discipline are eligible to apply for small travel grants of the American Council of Learned Societies. Financial assistance is limited to airfare between major commercial airports and will not exceed one-half of projected economy-class fare. Social scientists and legal scholars who specialize in the history or philosophy of their disciplines are eligible if the meeting they wish to attend is so oriented. Applicants must hold a Ph.D. degree or its equivalent, and must be citizens or permanent residents of the United States. To be eligible, proposed meetings must be broadly international in sponsorship or participation, or both. The deadlines for application to be received in the ACLS office are: meetings scheduled between July and October, March 1; for meetings scheduled between November and February, July 1; for meetings scheduled between March and June, November 1. Please request application forms by writing directly to the ACLS (Attention: Travel Grant Program), 228 East 45 Street, New York, NY 10017, setting forth the name, dates, place, and sponsorship of the meeting, as well as a brief statement describing the nature of your proposed role in the meeting.

### Deaths

Paul W. Conner, InterFuture, New York, NY, November 28, 1984.

George Montgomery, Kansas State University (retired), October 26, 1984.

Emanuel Stein, professor emeritus, department of economics, New York University, January 26, 1985.

### Retirement

Carl Kreider, professor of economics, Goshen College, June 30, 1985.

### Foreign Scholars

Luis F. Gonzales Vigil, Universidad Nacional Mayor de San Marcos, Lima, Peru: visiting professor of Latin American Studies, University of Pittsburgh, winter 1985.

Yasukichi Yasauba, Osaka University: visiting professor, University of Pittsburgh, winter 1985.

### Promotions

Annette E. Meyer: associate professor of economics, Trenton State College, September 1984.

William E. Mitchell: professor of economics, University of Missouri-St. Louis, September 1, 1983.

Donald L. Phares: professor of economics and public policy administration, University of Missouri-St. Louis, September 1, 1984.

Sherrill Shaffer: senior economist, Federal Reserve Bank of New York, November 15, 1984.

### Administrative Appointments

Stephen Dresch, International Institute for Applied Systems Analysis, Austria: dean, School of Business and Engineering Administration, Michigan Technological University, January 1, 1985.

Annette E. Meyer: chair, department of economics, Trenton State College, January 1985.

Robert L. Sorensen: chairman, department of economics, University of Missouri-St. Louis, September 1, 1984.

### Appointments

Carol W. Jones, Harvard University: assistant professor of economics and natural resources, University of Michigan, September 1, 1984.

Hassan Khademian, Michigan State University: assistant professor of economics, University of Missouri-St. Louis, September 1, 1984.

Hugh H. Macaulay, Jr., National Taiwan University: visiting professor, College of the Holy Cross, August 25, 1985.

Robert T. Michael: director, National Opinion Research Center, Chicago, September 1, 1984.

Robert N. Mottice, Ashland College: director of taxation and fiscal policy, National Association of Manufacturers, January 14, 1985.

Edgar A. Norton: assistant professor of finance, Northwest Missouri State University, August 13, 1984.

George Sofianos, Harvard University: assistant professor, Graduate School of Business Administration, New York University, September 1984.

Donald L. Westerfield, Southwestern Bell Telephone: adjunct professor of economics, Webster University, September 1, 1984.

#### Leaves for Special Appointments

Elizabeth M. Clayton, University of Missouri-St. Louis: director, Soviet Interview Project, University of Illinois-Champaign, September 1984.

#### NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, use the following style:

A. Please use the following categories (please—do not send public relation releases):

- |   |   |
|---|---|
| 1—Deaths  | 6—New Appointments                                  |
| 2—Retirements                                   | 7—Leaves for Special Appointments (NOT Sabbaticals) |
| 3—Foreign Scholars (visiting the USA or Canada) | 8—Resignations                                      |
| 4—Promotions                                    | 9—Miscellaneous                                     |
| 5—Administrative Appointments                   |   |

B. Please give the name of the individual (SMITH, Jane W.), her present place of employment or enrollment: her new title (if any), new institution and the date at which the change will occur.

C. Type each item on a separate 3×5 card.

D. The closing dates for each issue are as follows: *March*, October 15; *June*, January 15; *September*, April 15; *December*, July 15.

All items and information should be sent to the Assistant Editor, *American Economic Review*, 169 Nassau Street, Princeton, NJ 08542-7067.

## **Inflation, Stagflation, Relative Prices, and Imperfect Information**

**ALEX CUKIERMAN**

Professor Cukierman presents a summary view of the recent imperfect approach to inflation and its real effects, focusing on two types of informational limitations. The first involves situations in which individuals have asymmetric information about the current general price level and consequently confuse relative and aggregate changes in prices. The second considers models in which individuals cannot distinguish permanent from transitory changes in the economic environment. \$32.50

## **The Economics of Industrial Society**

**MICHIO MORISHIMA**

This study offers new ways of understanding the economic problems of industrialized countries, providing an effective critique of current economic theories and developing an original model of the economics (neoclassical, Marxist, Keynesian) of modern industrial society.

Throughout, the author orients his analysis toward solving problems in the real world and explaining the operations of economic institutions in different countries.

Cloth \$49.50 Paper \$15.95

## **Mathematical Economics**

**Second Edition**

**AKIRA TAKAYAMA**

This is a systematic exposition and survey of mathematical economics which emphasizes the unifying structures of economic theory.

It provides the reader with the technical tools and methodological approaches necessary for undertaking original research, gradually taking him from the elementary level to the frontiers of mathematical economics research.

Cloth about \$34.50 Paper about \$18.95

## **Growth, Acquisition and Investment**

***An Analysis of the Growth of Industrial Firms and  
Their Overseas Activities***

**MANMOHAN S. KUMAR**

Professor Kumar presents the results of an empirical investigation into four aspects of firm growth: the relationship between size, growth and profitability; the degree of trade-off between growth by acquisition and growth by new investment; the role of different forms of financing; and the implications of external markets and overseas production for firms' performance. \$37.50

## **The Philosophy of Economics**

***An Anthology***

**DANIEL M. HAUSMAN, Editor**

This anthology of essays on methodological problems in economics contains the classic discussions by figures such as Mill, Marx, Weber, Veblen, Keynes and many others. It also provides a sampling of work recently undertaken on this topic and includes a comprehensive introduction by the editor.

Cloth \$39.50 Paper \$14.95

**Cambridge  
University  
Press**

**A new edition . . .**

**Economic Theory in Retrospect**

**Fourth Edition**

**MARK BLAUG**

This new edition of a classic study in the history of economic thought, focusing on theories rather than theorists, is substantially revised and updated throughout, with major new sections on monetary theory and macroeconomics, and a new chapter on location theory.

From the reviews of previous editions:

"It is a magnificent achievement in the breadth of its scholarship, the incisiveness of its insights, and in the depth of its knowledge of economics past and present."—*The Economic Journal*

Cloth about \$69.50 Paper about \$27.95

**Marshall, Orthodoxy and the Professionalisation of Economics**

**JOHN MALONEY**

John Maloney explores the orthodoxy that economist Alfred Marshall constructed around his own theories and vision of the economics future.

Those who agree with Keynes that "the world is ruled by little else" but the ideas of economists and political philosophers will want to read this book for the light it sheds on how and why, early in this century, one set of economic ideas came to exert a dominance which has persisted to this day.

*Cambridge Studies in the History and Theory of Politics*

About \$47.50

**International Economic Policy Coordination**

**WILLIAM BUITER and RICHARD MARSTON, Editors**

This volume, based on a conference organized jointly by the Centre for Economic Policy Research, examines recent developments in international coordination of economic policy. About \$39.50

**Energy Policy in America Since 1945**

**A Study of Business-Government Relations**

**RICHARD H.K. VIETOR**

"This book should be read by anyone who is interested in energy policy, business history, or business-government relations—which means everyone."—Robert B. Stobaugh, *Harvard Business School*

Since the development of a sound energy policy for cheap fossil fuel—coal, petroleum, and gas—has become a central concern in shaping the economy, we have needed a balanced, authoritative account of the history of energy policy in the US, which, at last, we have in Richard Vietor's book. \$29.95

**An Economic Theorist's Book of Tales**

**Essays that Entertain the Consequences of New Assumptions in Economic Theory**

**GEORGE A. AKERLOF**

This book is a collection of essays exploring the consequences of making non-standard economic assumptions. It breaks with traditional economic theory, which relied upon a tacit and "classical" set of assumptions that have gradually acquired a life of their own in terms of how economists write, think, and justify economic models. Cloth \$29.95 Paper \$8.95

# AEA sponsored Group Life Insurance for you and your family— at attractive rates!

The AEA Group Life Insurance Plan can help provide valuable supplementary protection—at attractive rates—for eligible members and their dependents.

Because AEA participates in a large Insurance Trust which includes other scientific and technical organizations, the low cost may be even further reduced by premium credits. In the past eight years, insured members received credits on their April 1 semiannual payment notices averaging over 44% of their annual premium contributions. (These credits are based on the amount paid during the previous policy year ending September 30.) Of course future premium credits, and their amounts, cannot be promised or guaranteed.

Now may be a good time for you to re-evaluate your present coverage and look into AEA Life Insurance. Just fill out and return the coupon for more details at no obligation.

IN A NEW EDITION

## **PROGRAMS IN AID OF THE POOR**

FIFTH EDITION

**Sar A. Levitan**

While the Reagan administration's onslaught on the welfare system has not resulted in an appreciable drop in the total level of federal contributions to the poor, the increase in the number of poor—from 31.8 million in 1980 to 35.3 million three years later—has resulted in a sharp decline in per capita aid. In this extensive and timely revision of his classic work, Sar A. Levitan surveys all the existing federally funded programs in aid of the poor and evaluates the impact of the present administration's policies on welfare and assistance programs to America's needy.

**\$17.50 hardcover \$5.95 paperback**

## **ALTERNATIVE ROUTES TO FORMAL EDUCATION**

**edited by Hilary Perraton**

The demand for education is outstripping the capacity of many countries to build schools or to recruit and pay teachers. One of the alternatives to the traditional classroom—known as distance teaching—combines correspondence courses with radio or television broadcasts and occasional face-to-face study. This book examines the variety of ways in which distance teaching has been used, provides comparisons of specific cases, analyzes their costs, and considers the effectiveness of distance teaching versus traditional education.

*Published for the World Bank*

**\$14.95 paperback \$35.00 hardcover**

## **AGRICULTURAL DEVELOPMENT**

**An International Perspective**

REVISED AND EXPANDED EDITION

**Yujiro Hayami and Vernon W. Ruttan**

A basic reference in the field since its initial publication in 1971, this text here appears in an enlarged and updated new edition—and is made available in paperback for the first time. The authors identify the capacity to develop technology consistent with resource endowments as the single most important variable in the growth of agricultural productivity. In this new edition, they also test their hypothesis against new data and more recent development experience.

# BROOKINGS

## **Assessing Tax Reform**

**Henry J. Aaron and Harvey Galper**

The reform of the U.S. tax system is a central political issue. This book offers a concise, nontechnical evaluation to help general readers and students understand the tax reform issues Congress is now debating. The authors identify the major alternative proposals, analyze principles of taxation that can be used for judging them, and present their own program for a fair, efficient, and less complex tax structure.

April 1985/c. 175 pages/\$8.95 paper/\$22.95 cloth

## **Who Paid the Taxes, 1966-85?**

**Joseph A. Pechman**

In this sequel to the widely acclaimed Brookings book *Who Bears the Tax Burden?*, Pechman analyzes how the distribution of federal, state, and local taxes has changed in the past two decades. Presenting estimates based on a unique series of microdata sets, he concludes that the tax system became less progressive between 1966 and 1985, primarily because the corporation income and property taxes declined in importance while heavier emphasis was being placed on the payroll tax.

January 1985/84 pages/\$8.95 paper/\$22.95 cloth

## **Taxes, Loans, and Inflation**

**Eugene Steuerle**

Steuerle examines how the misallocation of capital results from the interaction of tax laws, the operation of the market for loanable funds, and inflation. Focusing on tax arbitrage and inflation-induced discrimination among taxpayers and borrowers, he analyzes the taxation of capital income and discusses several related issues. He concludes with a reform agenda that calls for the adoption of a broader-based, flatter-rate income tax.

May 1985/c. 230 pages/\$9.95 paper/\$26.95 cloth

## **OPEC's Investments and the International Financial System**

**Richard P. Mattione**

After sharply increasing oil prices in late 1973, members of the Organization of Petroleum Exporting Countries built up sizable financial holdings. Mattione is the first to analyze in detail how OPEC nations have used that wealth. This study surveys the size and distribution of each nation's investments; their effects on international financial markets; the financial, political, and developmental motives behind the investment strategies; and the outlook for the late 1980s.

January 1985/202 pages/\$9.95 paper/\$26.95 cloth

## **The Global Factory: Foreign Assembly in International Trade**

**Joseph Grunwald and Kenneth Flamm**

Firms in industrial countries are increasingly shifting labor-intensive production processes abroad to developing countries with an abundance of cheap labor. In this evaluation of foreign assembly, the authors first examine the semiconductor industry and then present case studies of the assembly industry in Mexico, Haiti, and Colombia. They analyze the domestic, political, social, and economic effects of the reorganization of industry abroad and discuss the policy implications for the United States and its manufacturing partners.

## **The Management Challenge**

Japanese Views

*edited by Lester C. Thurow*

The original contributions in this book present Japanese management as the Japanese see it. They show how an economy that has outperformed ours during the last 30 years works. Thurow's introductory essay and his comments on each contribution provide a unifying framework while pointing up the implications that each chapter raises for the reblending of the American economic mixture.

\$14.95

## **Market Structure and Foreign Trade**

*Elhanan Helpman and Paul R. Krugman*

Relating current theoretical work to the main body of trade theory, this book offers entirely new material on contestable markets, oligopolies, welfare, and multinational corporations, and new insights on external economies, intermediate inputs, and trade composition.

\$22.50

## **Deregulating the Airlines**

# JOURNAL OF ACCOUNTING & ECONOMICS

Published by North-Holland in collaboration with The Graduate School of Management, The University of Rochester

## Editors:

ROSS L. WATTS and JEROLD L. ZIMMERMAN,  
Graduate School of Management, University of  
Rochester, Rochester, NY 14627, USA

## Consulting Editor:

ROBERT S. KAPLAN,  
Graduate School of Industrial Administration,  
Carnegie-Mellon University, Pittsburgh, PA, USA.

The *Journal of Accounting and Economics* encourages the application of economic theory to the explanation of accounting phenomena. The theories of the firm, public choice, government regulation, and agency theory, in addition to financial economics, can contribute significantly to increasing our understanding of accounting. The *JAE* provides a forum for the publication of the highest quality manuscripts which employ economic analyses of accounting problems. A wide range of methodologies are encouraged and covered:

- the determination of accounting standards
- government regulation of corporate disclosure
- the information content and role of accounting numbers in capital markets
- the role of accounting in financial contracts and in monitoring agency relationships
- the theory of the accounting firm
- government regulation of the accounting profession
- statistical sampling and the loss function in auditing
- the role of accounting within the firm (managerial accounting)

## CONTENTS OF SPECIAL VOLUME 7 (March 1985):

### Management Compensation and the Managerial Labor Market

Kevin J. Murphy, Corporate Performance and Managerial Remuneration, An Empirical Analysis; Anne T. Coughlan and Ronald M. Schmidt, Executive Compensation, Management Turnover, and Firm Performance: An Empirical Investigation; George J. Benston, The Self-Serving Management Hypothesis: Some Evidence; Paul M. Healy, The Effect of Bonus Schemes on Accounting Decisions; Robert S. Kaplan, Comments on Paul Healy, "The Effect of Bonus Schemes on Accounting Decisions"; James A. Brickley, Sanjai Bhagat and Ronald C. Lease, The Impact of Long-Range Managerial Compensation Plans on Shareholder Wealth; Hassan Tehrani and James F. Waageleijn, Market Reaction to Short Term Executive Compensation Plan Adoption; Jerold B. Warner, Stock Market Reaction to Management Incentive Plan Adoption: Overview; W. Bruce Johnson, Robert P. Magee, Nandu J. Nagarajan and Harry A. Newman, An Analysis of the Stock Price Reaction to Sudden Executive Deaths: Implications for the Managerial Labor Market; G. William Schwert, A Discussion of C.E.O. Deaths and the Reaction of Stock Prices; Richard A. Lambert and David F. Larcker, Golden Parachutes, Executive Decision-Making, and Shareholder Wealth; Sherwin Rosen, Commentary on "Golden Parachutes, Executive Decision-Making, and Shareholder Wealth"; Wilbur Lewellen, Claudio Loderer and Ahron Rosenfeld, Merger Decisions and Executive Stock Ownership in Acquiring Firms; Wayne H. Mikkelsen and Richard S. Ruback, Takeovers and Managerial Compensation: A Discussion; Artur Raviv, Management Compensation and the Managerial Labor Market: An Overview; William H. Meckling, Three Reflections on Performance Rewards and Higher Education.

## **CORPORATE CAPITAL STRUCTURES IN THE UNITED STATES**

*Edited by Benjamin M. Friedman*

Continuing the project begun in *The Changing Roles of Debt and Equity in Financing U.S. Capital Formation*, this volume focuses on the financial side of capital formation, particularly the issue of financing capital through debt and equity. It is a useful compendium on corporate finance for those involved in decisions on financing corporate investment as well as academics interested in the financial structure of U.S. corporations and the relationship of corporate needs for capital to the needs of the government.

*An NBER Project Report*  
Cloth \$48.00 408 pages

## **FEDERAL TAX POLICY AND CHARITABLE GIVING**

*Charles T. Clotfelter*

In this study, Clotfelter demonstrates that changes in tax policy — effected through legislation or inflation — can have a significant influence on the level and composition of charitable giving. Clotfelter focuses on empirical analysis of the effects of tax policy on charitable giving in four major areas: individual contributions, volunteering, corporate giving, and charitable bequests. The result is a model for policy-oriented research efforts as well as a timely contribution to the evidence that must inform proposals for tax reform.

*An NBER Monograph*  
Cloth \$39.00 336 pages

## **THE INTERNATIONAL TRANSMISSION OF INFLATION**

*Michael R. Darby, James R. Lothian,  
Arthur E. Gandolfi, Anna J. Schwartz,  
and Alan C. Stockman*

How does inflation catch fire and spread from country to country? This book offers comprehensive answers, including the controversial argument that the United States, through its policy of monetary growth, was the primary instigator of inflation both at home and abroad during the 1970s. The authors draw their conclusions from a multicountry data base and a model of international transmission more complete than any other yet constructed.

*An NBER Monograph*  
Paper \$22.50 744 pages

## **SOCIAL EXPERIMENTATION**

*Edited by Jerry A. Hausman and  
David A. Wise*

Since 1970 the United States government has spent over half a billion dollars on social experiments intended to assess the effect of potential tax policies, health insurance plans, housing subsidies, and other programs. The contributors to this volume consider, among other questions, whether these experiments were worth their cost, whether they revealed information that could not have been learned by other means, and whether the experiments could have been better designed and analyzed.

### Production, Income, and Welfare

The Search for an Optimal Social Order

By Jan Tinbergen

*Production, Income, and Welfare* focuses on the recurring theme of Tinbergen's work, drawing together his various concerns: using basic tools of economic and econometric analysis, Tinbergen attempts to discover scientifically the best socioeconomic policy and the optimum mix of the market and planned elements of the economy.

Jan Tinbergen was the first economist to receive the Nobel Prize in Economics (1969), a just reward for his contributions to the discipline. His work has ranged widely, covering such diverse areas as econometrics, business cycles, income distribution, and production functions, and in each he has been responsible for important advances.

### WORKS LIKE LOTUS' 1-2-3, WITH FEATURES LIKE SAS

- ySTAT combines the best of microcomputer (Lotus 1-2-3) and the best of mainframe (SAS) in ONE. Yes, in ONE.
- It is almost effortless to use ySTAT even for the first time. And if you are familiar with Lotus 1-2-3 or any other spreadsheet program, you are ready to start using ySTAT. As in 1-2-3, you simply move the cursor to the appropriate menu or submenus and make your selection.
- Lets you enter or read data into the spreadsheet so that you can see the data on the screen by scrolling sideways or up and down the spreadsheet. You may enter, edit, copy, move, delete, select or do whatever you like to the data.
- ySTAT features advanced windowing technique for selecting variable names and displaying outputs and tables.
- Uses dynamic memory allocation to give you the maximum amount of memory for each procedure (PROC) that you may use at any time. You do not have to swap disks all the time.
- Accepts data received from time sharing systems, or data generated by other PC programs. It reads individual raw data for up to 255 variables per record as well as multi-way tables as input. The data may be numeric, alphabetic, or hybrid, with or without missing values.
- ySTAT simplifies data transformation by performing vector matrix operations from cell formula that only one formula is required for creating a whole column of values for a new variable.
- It includes the following procedures (PROC): Means, Frequency, Summary, Correlate, Crosstab, Table, ANOVA, OLS, WLS, 2SLS, Autoregression, Pooling of time series and Cross section, etc.
- ySTAT is a fast, highly accurate, economical, and, in many ways, superior alternative to main frame computing. Unlike the mainframe and many of its micro-offsprings which display a large data set or table in fragmented parts and line by line, ySTAT's screen displays are rapidly presented as screen pages and can be scrolled or flipped over in all directions with a touch of one or two keys. A large table or data can be viewed continuously.

#### SYSTEM REQUIREMENTS

IBM PERSONAL COMPUTER (PC, XT, AT), or other MS DOS compatibles; 1 floppy disk drive or a hard disk system; DOS 2.0 or 3.0 and 256K memory; with or without 8087/80287 math chip.

PRICE: \$395. Demo disk available at \$5.

Introductory price at \$295 for the first 1000 inquirers (including demo purchasers).

**ROBERT A. DAHL**

## **A Preface to Economic Democracy**

Dahl, author of the classic, *A Preface to Democratic Theory*, claims we can achieve a society of true social and political equality without sacrificing liberty by making a radical extension of democracy to the economic order. He presents an empirically informed and philosophically acute defense of "work-place democracy" that challenges our common assumptions and makes the startling proposal that only a radical transformation of American social vision can truly reconcile the demands of liberty, justice, and efficiency. \$14.95

**JOHN M. QUIGLEY & DANIEL L. RUBINFELD, Editors**

## **American Domestic Priorities**

### **An Economic Appraisal**

High deficits, large military and social security expenditures, and the "New Federalism" have put the future of many domestic programs in doubt. Twenty-six nationally prominent economists address questions fundamental to the design of education, housing, transportation, environmental, and anti-poverty policy, proposing imaginative alternatives to further budget cuts for reducing the federal deficit. \$32.50 cloth, \$9.95 paperback

**LINDA ALEXANDER RODRIGUEZ**

## **The Search for Public Policy**

### **Regional Politics and Government Finances in Ecuador, 1830-1940**

Based on meticulous research into Ecuadorian, U.S., and British archives, this study of the evolution of an active state in Ecuador during the first century of its national existence cuts through the political and ideological propaganda that has obscured the country's history. \$32.50

**LORNA M. DANIELLS**

## **Business Information Sources**

### **New, Revised Edition**

Here is the long-awaited revised edition of this essential guide to business books and reference sources. Aimed at the practicing business person as well as the business student and the librarian, this guide has been hailed as "an absolutely indispensable book for any library that ever has a business question" (*Choice*). \$24.95

**M. I. FINLEY**

## **The Ancient Economy**

### **Second Edition, new in paperback**

This book examines the various aspects of what we call the economy of the Graeco-Roman world with the concepts appropriate to their behavior and values. \$8.95

# ENERGY FACTS AND FIGURES

Robert H. Romer, Amherst College

A concise and useful energy handbook containing the essential data that anyone needs when dealing with the energy problem—72 pages of tables and graphs showing the history of energy production and consumption in the world and the United States from 1850 to 1983, with a detailed examination of energy use in the United States in 1983.

Carefully compiled by Robert H. Romer, Professor of Physics at Amherst College, and based in part on the extensive appendices to his earlier energy book, **Energy Facts and Figures** includes world-wide and U.S. electrical generating capacity, per capita GNP and power consumption figures since 1900, consumer prices of common sources of energy, solar energy and degree-day data, the energy content of various fuels, the dimensions and composition of the earth, its atmosphere and its oceans, the earth's water cycles and energy flows, energy requirements for various modes of transportation and for common electrical appliances, an amortization table for comparing capital and operating costs, and more. An extensive table of conversion factors is included.

\$8.95 postpaid. ISBN 0-931691-17-6 (paper)

The American Economics Association (AEA) is now soliciting applications to host the AEA Summer Program for Minority Students, for three summers beginning in 1986.

This program is now in its twelfth year and is currently at the University of Wisconsin at Madison. Previous host institutions have been Berkeley, Northwestern, and Yale.

The intent of the program is to increase the number of Blacks, Hispanics, and Native Americans pursuing the Ph.D. in Economics. In recent years the course of study has been an intensive eight to ten week program in intermediate microeconomics and macroeconomics, at the honor's level, and courses in econometrics or mathematical economics.

Funding for the program has been provided by the hosting institutions and grants to the AEA. Applications should be sent to Professor Donald J. Brown, chairman of the AEA Committee on the Status of Minority Groups in the Economics Profession, CSMGEP, no later than September 1, 1985.

CSMGEP  
Attention: Donald J. Brown  
Chairman, Department of Economics  
Yale University

## Is it better to be a big frog in a small pond or a small frog in a big pond?

Robert H. Frank argues that people's concerns about status affect a surprisingly broad range of economic choices, from salaries to laws and regulations.

"*Choosing the Right Pond* is bound to change the way economists, philosophers, and others think about a great variety of topics ranging from safety regulations and consumers' savings to general principles of distributive justice and social contract theory . . . the book is a landmark in social thought."

David Braybroke  
Dalhousi University, Canada

"Frank is obviously onto something fundamental in his treatment of envy and status as factors in human behavior . . . I couldn't put *Choosing the Right Pond* down."

E.O. Wilson  
author, *On Human Nature*

"It is a rare combination: a book that is profound and fun to read."

James M. Buchanan  
author, *Calculus of Consent*

## Computer Access to Articles in the JEL Subject Index

On-line computer access to the *JEL* and *Index of Economic Articles* data base of journal articles is currently available through DIALOG Information Retrieval Service. DIALOG file 139 (*Economic Literature Index*) contains complete bibliographic citations to articles from some 260 journals listed in the quarterly *JEL* issues from 1969 through the current issue. The abstracts in *JEL* since June 1984 are also available as part of the full bibliographic record. The file may be searched using free-text searching techniques or author, journal, title, geographic area, date, and other descriptors, including descriptor codes based on the *Index's* four-digit subject classification numbers.

DIALOG offers a variety of contract choices, including the option to pay for only what you use—*no minimum, no initiation or start-up fee*. Most university libraries already subscribe to DIALOG. For information on the DIALOG service, contact your librarian or write to or call:

DIALOG Information Services, Inc., Marketing Department, 3460 Hillview Avenue, Palo Alto, California 94304 (800/227-1927 or 800/982-5838, in California, or 415/858-3785).

**MATHEMATICAL AND STATISTICAL PROGRAMMING PACKAGE FOR YOUR IBM PC**  
**FAST • EASY TO USE • POWERFUL**

# GAUSS™

**YOU'VE NEVER SEEN ANYTHING LIKE IT!**

**GAUSS** is a sophisticated mathematical and statistical programming package for the IBM PC and compatibles. It combines speed, power, and ease of use in one amazing program.

**GAUSS** allows you to do essentially anything you can do with a mainframe statistical package — and a lot more.

Personal computers are friendly, convenient, and inexpensive. So is **GAUSS**. **GAUSS** is not just a stripped-down mainframe program. **GAUSS** has been designed from the ground up to take advantage of all of the conveniences of a personal computer. After trying **GAUSS**, you may never use a mainframe again.

**GAUSS** comes with programs written in its matrix programming language that allow you to do most econometric procedures, including OLS, 2SLS, 3SLS, PROBIT, LOGIT, MAXIMUM LIKELIHOOD, and NON-LINEAR LEAST SQUARES.

In the current version, **GAUSS** will accept up to 90 variables in a regression. There is no limit on the number of observations.

**GAUSS** will do a regression with 10 independent variables and 800 observations in under 4 seconds — and with 50 variables and 10,000 observations in under 18 minutes. It will compute the maximum likelihood estimates of a binary logit model, with 10 variables and 1,000 observations, in 1-2 minutes, depending upon the number of iterations required.

**GAUSS** allows you to do complicated statistical procedures that you would never imagine trying on a mainframe. It is easy to program almost any routine, and **GAUSS** is so fast that it can do almost any job. But the nicest thing of all is that the cost of time on your personal computer is essentially zero!

**GAUSS** is an excellent teaching tool. It makes programming easy and allows students to focus on concepts and techniques.

If you can write it mathematically, you can write it in **GAUSS**. Furthermore, you can write it in **GAUSS** almost exactly the way you would write it mathematically.

**GAUSS** is 10-15 times faster than other programs that use the 8087, and 15-100 times faster than other programs that do not use the 8087.

As in APL, single statements in **GAUSS** can accomplish what might take dozens of lines in another language. However, **GAUSS** provides you with additional powerful numerical operators and functions — especially for statistics and the solution of linear equations — that are not found in APL. And, of course, the syntax in **GAUSS** is much more natural (for most of us) than that in APL.

**GAUSS** has state-of-the-art numerical routines and random number generators.

**GAUSS** is extremely accurate. It allows you to do an entire regression in 19 digit accuracy. It will compute the Longley benchmark coefficients in 5 hundredths of a second with an average of 11 correct digits! (Try that on a mainframe!)

**GAUSS**, with its built-in random number generators and powerful functions and operators, is an excellent tool for doing simulations.

## **GAUSS and the 8087 NUMERIC DATA PROCESSOR GIVE YOU MINICOMPUTER PERFORMANCE ON YOUR DESKTOP.**

### **SPECIAL INTRODUCTORY OFFER**

With 30 Day Money

Back Guarantee ..... Reg. 395.00 **\$250.00**

# OECD publications

ORGANIZATION FOR ECONOMIC COOPERATION AND DEVELOPMENT

## **National Accounts, Volume I: Main Aggregates, 1960-1983**

After a summary of the definitions of these main aggregates, this volume is divided into five parts. Part one contains graphs for each country showing growth in real terms of GDP and expenditure. Part two gives for the OECD as a whole and for each country the main aggregates in national currencies. Part three provides "growth triangles" for the main components of final expenditure. Part four gives a set of comparative tables (US dollars, volume and price indices, population and exchange rates), with totals for groups of countries and for the OECD as a whole. Finally, part five contains a set of comparative tables using PPPs.

1985 130 pages \$18.00

## **Geographical Distribution of Financial Flows to Developing Countries, 1980-1983**

The unique source of data on the sources, volume and terms of official aid flows to 110 developing countries. It also gives the origin, type, and inflow of other external financial resources as well as some basic economic information for each developing country covered.

1984 290 pages \$32.00

## **Costs and Margins in Banking: Statistical Supplement 1978-1982**

As a statistical supplement to the 1980 OECD report on *Costs and Margins in Banking: An International Survey*, this volume provides a unique tool for analyzing developments during the period 1978-1982.

1985 112 pages \$25.00

## **The Internationalisation of Banking: The Policy Issues**

*R. M. Pecchioli*

Examines the implications of the expansion of world credit and the emergence of banks as channels for balance-of-payments financing.

1983 222 pages \$22.00

## **Transfer Pricing and Multinational Enterprises: Three Taxation Issues**

The three reports published in this volume supplement the 1979 report of the same name. They consider problems for multinational enterprises resulting from the adjustment of transfer prices by tax authorities, transfer pricing in the banking sector, and the allocation of management and service costs for tax purposes.

1984 92 pages \$12.00
